1 | Preface

This book has been written as an introduction to programming for novice programmers. It is used in the first programming course at the University of Copenhagen's bachelor in computer science program. It has been typeset in L^AT_EX, and all programs have been developed and tested in Mono version 5.10.1.57.

2 | Introduction

Programming is a creative process in which exciting problems may be solved and new tools and applications may be created. With programming skills, you can create high-level applications to run on a mobile device that interact with other users, databases, and artificial intelligence; you may create programs that run on supercomputers for simulating weather systems on alien planets or social phenomena in the internet economy; and you may create programs that run on small custom-made hardware for controlling your home appliances.

2.1. How to Learn to Solve Problems by Programming

In order to learn how to program, there are a couple of steps that are useful:

1. Choose a programming language: A programming language, such as F#, is a vocabulary and a set of grammatical rules for instructing a computer to perform a certain task. It is possible to program without a concrete language, but your ideas and thoughts must still be expressed in some fairly rigorous way. Theoretical computer scientists typically do not rely on computers nor programming languages but uses mathematics to prove properties of algorithms. However, most computer scientists program using a computer, and with a real language you have the added benefit of checking your algorithm, and hence your thoughts, rigorously on a real computer. This book teaches a subset of F#. The purpose is not to be a reference guide to this language but to use it as a vessel to teach you, the reader, how to convert your ideas into programs.
2. Learn the language: A computer language is a structure for thought, and it influences which thoughts you choose to express as a program, and how you choose to do it. Any conversion requires you to acquire a sufficient level of fluency in order for you to be able to make programs. You do not need to be a master in F# nor to know every corner of the language, and you will expand your knowledge as you expose yourself to solving problems in the language, but you must invest an initial amount of time and energy in order to learn the basics of the language. This book aims at getting you started quickly, which is why we intentionally teach just a small subset of F#. On the internet and through other works you will be able to learn much more.
3. Practice: In order to be a good programmer, the most essential step is: practice, practice, practice! It has been estimated that to master anything, then you have to have spent at least 10000 hours practicing, so get started logging hours! It of course matters, how you practice. This book teaches a number of different programming themes. The point is that programming is thinking, and the scaffold you use shapes

2. Introduction

your thoughts. It is therefore important to recognize this scaffold and to have the ability to choose one which suits your ideas and your goals best. The best way to expand your abilities is to sharpen your present abilities, push yourself into new territory, and try something new. Do not be afraid to make errors or be frustrated at first. These are the experiences that make you grow.

4. Solve real problems: I have found that using my programming skills in real situations with customers demanding specific solutions, has forced me to put the programming tools and techniques that I use into perspective. Sometimes a task requires a cheap and fast solution, other times customers want a long-perspective solution with bug fixes, upgrades, and new features. Practicing solving real problems helps you strike a balance between the two when programming. It also allows makes you a more practical programmer, by allowing you to recognize its applications in your everyday experiences. Regardless, real problems create real programmers.

2.2. How to Solve Problems

Programming is the act of solving a problem by writing a program to be executed on a computer. A general method for solving problems, given by George Pólya [9] and adapted to programming, is:

Understand the problem: To solve any problem it is crucial that the problem formulation is understood. What is to be solved? Do you understand everything in the description of the problem? Is all information for finding the solution available or is something missing?

Design a plan: Good designs lead to programs are faster to implement, easier to find errors in, and easier to update in the future. Before you start typing a program consider things like: What are the requirements and constraints for the program? Which components should the program have? How are these components supposed to work together? Designing often involves drawing a diagram of the program and writing program sketches on paper.

Implement the plan: Implementation is the act of transforming a program design into code. A crucial part of any implementation is choosing which programming language to use. Furthermore, the solution to many problems will have a number of implementations which vary in how much code they require, to which degree they rely on external libraries, which programming style they are best suited for, what machine resources they require, and how long time they take to run on a computer. With a good design, the coding is usually easy, since the design will have uncovered the major issues and found solutions for these, but sometimes implementation reveals new problems, which require rethinking the design. Most often the implementation step also require a careful documentation of key aspects of the code, e.g., a user manual for the user, and internal notes for fellow programmers that are to maintain and update the code in the future.

Reflect on the result: A crucial part of any programming task is ensuring that the program solves the problem sufficiently. Ask yourself questions such as: What are the program's errors, is the documentation of the code sufficient and relevant for its intended use? Is the code easily maintainable and extendable by other programmers? Which parts of your method would you avoid or replicate in future programming sessions? Can you reuse some of the code you developed in other programs?

Programming is a very complicated process, and Pólya's list is a useful guide but not a fail-safe approach. Always approach problem-solving with an open mind.

2.3. Approaches to Programming

This book focuses on several fundamentally different approaches to programming:

Imperative programming emphasizes *how a program shall accomplish a solution* and focusses less on *what the solution is*. A cooking recipe is an example of the spirit of imperative programming, where the recipe emphasizes what should be done in each step rather than describing the result. For example, a recipe for bread might tell you to first mix yeast and water, then add flour, etc. In imperative programming what should be done are called *statements* and in the recipe analogy, the steps are the statements. Statements influence the computer's *states*, in the same way that adding flour changes the state of our dough. Almost all computer hardware is designed to execute low-level programs written in imperative style. Imperative programming builds on the Turing machine [10]. As a historical note, the first major language was FORTRAN [6] which emphasized an imperative style of programming.

- imperative programming

- statement
- state

Declarative programming emphasizes *what a program shall accomplish* but not *how*. We will consider Functional programming as an example of declarative programming. A *functional programming* language evaluates *functions* and avoids state changes. The program consists of *expressions* instead of statements. As an example, the function $f(x) = x^2$ takes a number x , evaluates the expression x^2 , and returns the resulting number. Everything about the function may be characterized by the relation between the input and output values. Functional programming has its roots in lambda calculus [1]. The first language emphasizing functional programming was Lisp [7].

- declarative programming

- functional programming
- function
- expression

Structured programming emphasizes organization of programs in units of code and data. For example, a traffic light may consist of a state (red, yellow, green), and code for updating the state, i.e., switching from one color to the next. We will focus on Object-oriented programming as the example of structured programming. *Object-oriented programming* is a type of programming, where the code and data are structured into *objects*. E.g., a traffic light may be an object in a traffic-routing program. The first object-oriented programming language was Simula 67 developed by Dahl and Nygaard at the Norwegian Computing Center in Oslo [2].

- structured programming

- Object-oriented programming
- object

Event-driven programming, which is often used when dynamically interacting with the real world. This is useful, for example, when programming graphical user interfaces, where programs will often need to react to a user clicking on the mouse or to text arriving from a web-server to be displayed on the screen. Event-driven programs are often programmed using *call-back functions*, which are small programs that are ready to run when events occur.

- event-driven programming

- call-back functions

Most programs do not follow a single programming paradigm as, e.g., one of the above, but are a mix. Nevertheless, this book will treat each paradigm separately to emphasize its advantages and disadvantages.

2.4. Why Use F#

This book uses F#, also known as Fsharp, which is a functional first programming language, meaning that it is designed as a functional programming language that also supports imperative and object-oriented programming. It was originally developed for Microsoft's .Net platform but is available as open source for many operating systems through Mono. As an introduction to programming, F# is a young programming language still under development, with syntax that at times is a bit complex. Still, it offers a number of advantages:

Interactive and compile mode: F# has an interactive and a compile mode of operation.

In interactive mode you can write code that is executed immediately in a manner similar to working with a calculator, while in compile mode you combine many lines of code possibly in many files into a single application, which is easier to distribute to people who are not F# experts and is faster to execute.

Indentation for scope: F# uses indentation to indicate scope. Some lines of code belong together and should be executed in a certain order and may share data. Indentation helps in specifying this relationship.

Strongly typed: F# is strongly typed, reducing the number of runtime errors. That is, F# is picky, and will not allow the programmer to mix up types such as numbers and text. This is a great advantage for large programs.

Multi-platform: F# is available on Linux, Mac OS X, Android, iOS, Windows, GPUs, and browsers via the Mono platform.

Free to use and open source: F# is supported by the Fsharp foundation (<http://fsharp.org>) and sponsored by Microsoft.

Assemblies: F# is designed to be able to easily communicate with other .Net and Mono programs through the language-independent, platform-independent bytecode called Common Intermediate Language (CIL) organized as assemblies. Thus, if you find that certain parts of a program are easy to express in F# and others in C++, then you will be able to combine these parts later into a single program.

Modern computing: F# supports all aspects of modern computing including Graphical User Interfaces, Web programming, Information rich programming, Parallel algorithms, ...

Integrated development environments (IDE): F# is supported by major IDEs such as Visual Studio (<https://www.visualstudio.com>) and Xamarin Studio (<https://www.xamarin.com>).

2.5. How to Read This Book

Learning to program requires mastering a programming language, however, most programming languages contain details that are rarely used or used in contexts far from a specific programming topic. Hence, this book only includes a subset of F# but focuses on language structures necessary to understand several common programming paradigms: Imperative programming mainly covered in Chapters 6 to 11, functional programming mainly covered

2. Introduction

in Chapters 13 to 16, object-oriented programming in Chapters 20 and 22, and event-driven programming in Chapter 23. A number of general topics are given in the appendix for reference. For further reading please consult <http://fsharp.org>.

3 | Executing F# Code

3.1. Source Code

F# is a functional first programming language, meaning that it has strong support for functional programming, but also supports imperative and object-oriented programming.

F# has two modes of execution, *interactive* and *compiled*. Interactive mode allows the user to interact with F# as a dialogue: The user writes statements, and F# responds immediately. Interactive mode is well suited for small experiments or back-of-an-envelope calculations, but not for programming in general. In compile mode, the user writes a complete program, which is translated or compiled using the F# compiler into a compiled file. The compiled file can be run or executed as a stand-alone program using a virtual machine called `mono`. In both the interactive and compile mode, F# statements are translated into something that can be executed on the computer. A major difference is that in interactive mode, the translation is performed everytime the program is executed, while in compiled mode the translation is performed only once.

Both interactive and compile modes can be accessed via the *console*, see Appendix A for more information on the console. The interactive system is started by calling `fsharpi` at the command prompt in the console, while compilation is performed with `fsharpc`, and execution of the compiled code is performed using the `mono` command.

F# programs come in many forms, which are identified by suffixes. The *source code* is an F# program written in human-readable form using an editor. F# recognizes the following types of source code files:

<code>.fs</code>	An <i>implementation file</i> , e.g., <code>myModule.fs</code>	· implementation file
<code>.fsi</code>	A <i>signature file</i> , e.g., <code>myModule.fsi</code>	· signature file
<code>.fsx</code>	A <i>script file</i> , e.g., <code>gettingStartedStump.fsx</code>	· script file
<code>.fsscript</code>	Same as <code>.fsx</code> , e.g., <code>gettingStartedStump.fsscript</code>	

Compiled code is source code translated into a machine-readable language, which can be executed by a machine. Compiled F# code is either:

<code>.dll</code>	A <i>library file</i> , e.g., <code>myModule.dll</code>	· library file
<code>.exe</code>	A stand-alone <i>executable file</i> , e.g., <code>gettingStartedStump.exe</code>	· executable file

The implementation, signature, and script files are all typically compiled to produce an executable file, in which case they are called *scripts*, but can also be entered into the

interactive system, in which case these are called *script-fragments*. The implementation and signature files are special kinds of script files used for building libraries. Libraries in F# are called modules, and they are collections of smaller programs used by other programs, which will be discussed in detail in Chapter 9.

3.2. Executing Programs

Programs may either be executed by the interpreter or by compiling and executing the compiled code. In Mono the interpreter is called `fsharpi` and can be used in two ways: interactively, where a user enters one or more script-fragments separated by the “`;;`” characters, or to execute a script file treated as a single script-fragment.¹

To illustrate the difference between interactive and compile mode, consider the program in Listing 3.1.

Listing 3.1 `gettingStartedStump.fsx`:
A simple demonstration script.

```
1 let a = 3.0
2 do printfn "%g" a
```

The code declares a value `a` to be the decimal value 3.0 and finally prints it to the console. The `do printfn` is a statement for displaying the content of a value to the screen, and “`%g`” is a special notation to control how the value is printed. In this case, it is printed as a decimal number. This and more will be discussed at length in the following chapters. For now, we will concentrate on how to interact with the F# interpreter and compiler.

An interactive session is obtained by starting the console, typing the `fsharpi` command, typing the lines of the program, and ending the script-fragment with “`;;`”. The dialogue in Listing 3.2 demonstrates the workflow. What the user types has been highlighted by a box.

¹Jon: Too early to introduce lexeme: “F# uses many characters which at times are given special meanings, e.g., the characters “`;;`” is compound character denoting the end of a script-fragment. Such possibly compound characters are called lexemes.”

Listing 3.2: An interactive session.

```

1  $ fsharpi
2
3  F# Interactive for F# 4.1 (Open Source Edition)
4  Freely distributed under the Apache 2.0 Open Source License
5
6  For help type #help;;
7
8  > let a = 3.0
9    - do printfn "%g" a;;
10  3
11
12  val a : float = 3.0
13  val it : unit = ()
14
15  > #quit;;

```

We see that after typing `fsharpi`, the program starts by stating details about itself. Then F# writes `>` indicating that it is ready to receive commands. The user types `let a = 3.0` and presses `enter`, to which the interpreter responds with `-`. This indicates that the line has been received, that the script-fragment is not yet completed, and that it is ready to receive more input. When the user types `do printfn "%g" a;;` followed by `enter`, then by `;;` the interpreter knows that the script-fragment is completed, it interprets the script-fragment, responds with `3` and some extra information about the entered code, and with `>` to indicate that it is ready for more script-fragments. The interpreter is stopped when the user types `#quit;;`. It is also possible to stop the interpreter by typing `ctrl-d`.

The interactive session results in extra output on the *type inference* performed. In Listing 3.2 F# states that the name `a` has *type* `float` and the value `3.0`. Likewise, the `do` statement F# refers to by the name `it`, and it has the type `unit` and value `()`. Types are very important to F# since they define how different program pieces fit together like lego bricks. They are a key ingredients for finding errors in programs, also known as *debugging*, and much of the rest of this book is concerned with types.

Instead of running `fsharpi` interactively, we can write the script-fragment from Listing 3.1 into a file, here called `gettingStartedStump.fsx`. This file can be interpreted directly by `fsharpi` as shown in Listing 3.3.

Listing 3.3: Using the interpreter to execute a script.

```

1  $ fsharpi gettingStartedStump.fsx
2  3

```

Notice that in the file, `;;` is optional. We see that the interpreter executes the code and prints the result on screen without the extra type information as compared to Listing 3.2.

Finally, the file containing Listing 3.1 may be compiled into an executable file with the program `fsharpc`, and run using the program `mono` from the console. This is demonstrated in Listing 3.4.

Listing 3.4: Compiling and executing a script.

```

1 $ fsharpc gettingStartedStump.fsx
2 F# Compiler for F# 4.1 (Open Source Edition)
3 Freely distributed under the Apache 2.0 Open Source License
4 $ mono gettingStartedStump.exe
5 3

```

The compiler takes `gettingStartedStump.fsx` and produces `gettingStarted.exe`, which can be run using `mono`.

Both the interpreter and the compiler translates the source code into a format which can be executed by the computer. While the compiler performs this translation once and stores the result in the executable file, the interpreter translates the code every time the code is executed. Thus, to run the program again with the interpreter, it must be retranslated as `"$fsharpi gettingStartedStump.fsx"`. In contrast, compiled code does not need to be recompiled to be run again, only re-executed using `"$ mono gettingStartedStump.exe"`. On a MacBook Pro, with a 2.9 GHz Intel Core i5, the time the various stages take for this script are:

Command	Time
<code>fsharpi gettingStartedStump.fsx</code>	1.88s
<code>fsharpc gettingStartedStump.fsx</code>	1.90s
<code>mono gettingStartedStump.exe</code>	0.05s

I.e., executing the script with `fsharpi` is slightly faster than by first compiling it with `fsharpc` and then executing the result with `mono` ($1.88s < 0.05s + 1.90s$), if the script were to be executed only once, but every future execution of the script using the compiled version requires only the use of `mono`, which is much faster than `fsharpi` ($1.88s \gg 0.05s$).

Executing programs with the interpreted directly from a file and compiling and executing the program is much preferred for programming complete programs, since the starting state is well defined, and since this better supports *unit-testing*, which is a method for debugging programs. Thus, **prefer compiling over interpretation**.

4 | Quick-start Guide

Programming is the art of solving problems by writing a program to be executed by a computer. For example, to solve the following problem,

Problem 4.1

What is the sum of 357 and 864?

we have written the program shown in Listing 4.1.

Listing 4.1 quickStartSum.fsx:

A script to add 2 numbers and print the result to the console.

```
1 let a = 357
2 let b = 864
3 let c = a + b
4 do printfn "%A" c
```

```
1 $ fsharp --nologo quickStartSum.fsx && mono quickStartSum.exe
2 1221
```

In the box the above, we see our program was saved as a script in a file called `quickStartSum.fsx`, and in the console we executed the program by typing the command `fsharp --nologo quickStartSum.fsx && mono quickStartSum.exe`. The result is then printed in the console to be 1221. Here, as in the rest of this book, we have used the optional flag `--nologo`, which informs `fsharp` not to print information about its version etc., thus making the output shorter. The `&&` notation tells the console to first run the command on the left, and if that did not report any errors, then run the command on the right. This could also have been performed as two separate commands to the console, and throughout this book we will use the above shorthand when convenient.

To solve the problem, we made program consisting of several lines, where each line was an *expressions*. The first expression, `let a = 357`, in line 1 used the `let` keyword to bind the value 357 to the name `a`. This is called a *let-binding* and makes the name synonymous with the value. Another notable point is that F# identifies 357 as an *integer number*, which is F#'s preferred number type, since computations on integers are very efficient, and since integers are very easy to communicate to other programs. In line 2 we bound the value 864 to the name `b`, and to the name `c` we bound the result of evaluating the sum `a + b` in line 3. Line 4 is a *do-binding*, as noted by the keyword `do`. Do-bindings are also sometimes called *statements*, and the `do` keyword is optional in F#. Here the value of `c` was printed to the console followed by a newline with the *printfn function*. A function

4. Quick-start Guide

in F# is an entity that takes zero or more arguments and returns a value. The function `printfn` is very special, since it can take any number of arguments and returns the special value `()` which has type `unit`. The `do` tells F# to ignore this value. Here `printfn` has been used with 2 arguments: `"%A"` and `c`. Notice that in contrast to many other languages, F# does not use parentheses to frame the list of arguments, nor does it use commas to separate them. In general, the `printfn` function always has 1 or more arguments, and the first is a *format string*. A *string* is a sequence of characters starting and ending with double quotation marks. E.g., `let s = "this is a string of characters"` binds the string `"this is..."` to the name `s`. For the `printfn` function, the format string may be any string, but if it contains format character sequences, such as `%A`, then format character sequence are replaced by the arguments to `printfn` which follows the format string. The format string must match the value *type*, that is, here `c` is of type integer, whereas the format string `%A` matches many types.

Types are a central concept in F#. In the script 4.1 we bound values of integer type to names. There are several different integer types in F#, here we used the one called `int`. The values were not *declared* to have these types, instead the types were *inferred* by F#. Typing these bindings line by line in an interactive session, we see the inferred types as shown in Listing 4.2.

Listing 4.2: Inferred types are given as part of the response from the interpreter.

```
1 > let a = 357;;
2 val a : int = 357
3
4 > let b = 864;;
5 val b : int = 864
6
7 > let c = a + b;;
8 val c : int = 1221
9
10 > do printfn "%A" c;;
11 1221
12 val it : unit = ()
```

The interactive session displays the type using the `val` keyword followed by the name used in the binding, its type, and its value. Since the value is also responded, the last `printfn` statement is superfluous. However, **it is ill-advised to design programs to be run in an interactive session, since the scripts need to be manually copied every time it is to be run, and since the starting state may be unclear.** Notice that `printfn` is automatically bound to the name `it` of type `unit` and value `()`. F# insists on binding all statements to values, and in lack of an explicit name, it will use `it`. Rumor has it that `it` is an abbreviation for "irrelevant".

The following problem,

Problem 4.2

What is the sum of 357.6 and 863.4?

uses *decimal point* numbers instead of integers. These numbers are called *floating point* numbers, and their internal representation is quite different to integer numbers used previously. Likewise, algorithms used to perform arithmetic are quite different from integers.

Now the program would look like Listing 4.3.

**Listing 4.3 quickStartSumFloat.fsx:
Floating point types and arithmetic.**

```

1  let a = 357.6
2  let b = 863.4
3  let c = a + b
4  do printfn "%A" c

1  $ fsharpc --nologo quickStartSumFloat.fsx && mono
    quickStartSumFloat.exe
2  1221.0

```

On the surface, this could appear as an almost negligible change, but the set of integers and the set of real numbers (floats) require quite different representations in order to be effective on a computer, and as a consequence, the implementation of their operations, such as addition, are very different. Thus, although the response is an integer, it has type `float` which is indicated by `1221.0` and which is not the same as `1221`. F# is very picky about types, and generally does not allow types to be mixed, as demonstrated in the interactive session in Listing 4.4.

Listing 4.4: Mixing types is often not allowed.

```

1  > let a = 357;;
2  val a : int = 357
3
4  > let b = 863.4;;
5  val b : float = 863.4
6
7  > let c = a + b;;
8     let c = a + b;;
9     -----^
10
11 stdin(4,13): error FS0001: The type 'float' does not match the
    type 'int'

```

We see that binding a name to a number without a decimal point is inferred to be an integer, while when binding to a number with a decimal point the type is inferred to be a float, and that our attempt of adding an integer and floating point value gives an error. The *error message* contains much information. First, it states that the error is in `stdin(4,13)`, which means that the error was found on standard-input at line 4 and column 13. Since the program was executed using `fsharpic quickStartSumFloat.fsx`, here standard input means the file `quickStartSumFloat.fsx` shown in Listing 4.3. The corresponding line and column are also shown in Listing 4.4. After the file, line, and column number, F# informs us of the error number and a description of the error. Error numbers are an underdeveloped feature in Mono and should be ignored. However, the verbal description often contains useful information for *debugging*. In the example we are informed that there is a type mismatch in the expression, i.e., since `a` is an integer, F# expected `b` to be one too. Debugging is the process of solving errors in programs, and here we can solve the error by either making `a` into a float or `b` into an int. The right solution depends on the application.

4. Quick-start Guide

F# is a functional first programming language, and one implication of this is that names have a *lexical scope*. A scope is the lines in a program where a binding is valid, and lexical scope means that to find the value of a name, F# looks for the value in the above lines. Furthermore, at the outermost level, rebinding is not allowed. If attempted, then F# will return an error as shown in Listing 4.5.

Listing 4.5 quickStartRebindError.fsx:
A name cannot be rebound.

```
1 let a = 357
2 let a = 864

-----

1 $ fsharp --nologo -a quickStartRebindError.fsx
2
3 quickStartRebindError.fsx(2,5): error FS0037: Duplicate
  definition of value 'a'
```

However, if the same code is executed in an interactive session, then rebinding does not cause an error, as shown in Listing 4.6.

Listing 4.6: Names may be reused when separated by the lexeme “;;”.

```
1 > let a = 357;;
2 val a : int = 357
3
4 > let a = 864;;
5 val a : int = 864
```

The difference is that the “;;” *lexeme* is used to specify the end of a *script-fragment*. A lexeme is a letter or word, which F# considers as an atomic unit. Script-fragments may be defined both in scripts and in interactive mode, and rebinding is not allowed at the outermost level in script-fragments. Even with the “;;” lexeme, rebinding is not allowed in compile-mode. In general, **avoid rebinding of names**.

Advice

In F#, *functions* are also values, and we may define a function `sum` as part of the solution to the above program, as shown in Listing 4.7.

Listing 4.7 quickStartSumFct.fsx:
A script to add 2 numbers using a user-defined function.

```
1 let sum x y = x + y
2 let c = sum 357 864
3 do printfn "%A" c

-----

1 $ fsharp --nologo quickStartSumFct.fsx && mono
  quickStartSumFct.exe
2 1221
```

Functions are useful to *encapsulate* code, such that we can focus on the transformation of data by a function while ignoring the details on how this is done. Functions are also

4. Quick-start Guide

useful for code reuse, i.e., instead of repeating a piece of code in several places, such code can be encapsulated in a function and replaced with function calls. This makes debugging and maintenance considerably simpler. Entering the function into an interactive session will illustrate the inferred type the function `sum` has: `val sum : x:int -> y:int -> int`. The “`->`” is the mapping operator in the sense that functions are mappings between sets. The type of the function `sum`, should be read as `val sum : x:int -> (y:int -> int)`, that is, `sum` takes an integer and returns a function, which takes an integer and returns an integer. This is an example of a higher-order function.

Type inference in F# may cause problems, since the type of a function is inferred based on the context in which it is defined. E.g., in an interactive session, defining the `sum` in one scope on a single line will default the types to integers, F#’s favorite type. Thus, if the next script-fragment uses the function with floats, then we will get an error message as shown in Listing 4.8.

Listing 4.8: Types are inferred in blocks, and F# tends to prefer integers.

```
1  val sum : x:int -> y:int -> int
2
3  > let c = sum 357.6 863.4;;
4     let c = sum 357.6 863.4;;
5     -----^^^
6
7  stdin(3,13): error FS0001: This expression was expected to
8     have type
9     'int'
10    but here has type
11    'float'
```

A remedy is to define the function in the same script-fragment as it is used, such as shown in Listing 4.9.

Listing 4.9: Type inference is per script-fragment.

```
1  > let sum x y = x + y
2  - let c = sum 357.6 863.4;;
3  val sum : x:float -> y:float -> float
4  val c : float = 1221.0
```

Alternatively, the types may be explicitly stated as shown in Listing 4.10.

Listing 4.10: Function argument and return types may be stated explicitly.

```
1  > let sum (x : float) (y : float) : float = x + y;;
2  val sum : x:float -> y:float -> float
3
4  > let c = sum 357.6 863.4;;
5  val c : float = 1221.0
```

The function `sum` has two arguments and a return type, and in Listing 4.10 we have specified all three. This is done using the “`:`” lexeme, and to resolve confusion, we must use parentheses around the arguments, such as `(y : float)`, otherwise F# would not be

4. Quick-start Guide

able to understand whether the type annotation was for the argument or the return value. Often it is sufficient to specify just some of the types, since type inference will enforce the remaining types. E.g., in this example, the “+” operator is defined for identical types, so specifying the return value of `sum` to be a float implies that the result of the “+” operator is a float, and therefore that its arguments must be floats, and finally then that the arguments for `sum` must be floats. However, in this book we advocate the following advice: **specify types unless explicitly working with generic functions.** Advice

In this chapter, we have scratched the surface of learning how to program by concentrating on a number of key programming concepts and how they are expressed in the F# language. In the following chapters, we will expand the description of F# with features used in all programming approaches.

5 | Using F# as a Calculator

In this chapter, we will exclusively use the interactive mode to illustrate basic types and operations in F#.

5.1. Literals and Basic Types

All programs rely on processing of data, and an essential property of data is its *type*. A *literal* is a fixed value like the number 3, and if we type the number 3 in an interactive session at the input prompt, then F# responds as shown in Listing 5.1.

Listing 5.1: Typing the number 3.

```
1 > 3;;
2 val it : int = 3
```

What this means is that F# has inferred the type to be *int* and bound it to the identifier *it*. For more on binding and identifiers see Chapter 6. Types matter, since the operations that can be performed on integers, are quite different from those that can be performed on, e.g., strings. Therefore, the number 3 has many different representations as shown in Listing 5.2.

Listing 5.2: Many representations of the number 3 but using different types.

```
1 > 3;;
2 val it : int = 3
3
4 > 3.0;;
5 val it : float = 3.0
6
7 > '3';;
8 val it : char = '3'
9
10 > "3";;
11 val it : string = "3"
```

Each literal represents the number 3, but their types are different, and hence they are quite different values. The types *int* for integer numbers, *float* for floating point numbers, *bool* for Boolean values, *char* for characters, and *string* for strings of characters are the most

Table 5.1.: List of some of the basic types. The most commonly used types are underlined. For a description of integer see Appendix B.1, for floating point numbers see Appendix B.2, for ASCII and Unicode characters see Appendix C, for objects see Chapter 20, and for exceptions see Chapter 18.

common types of literals. A table of all *basic types* predefined in F# is given in Table 5.1. In addition to these built-in types, F# is designed such that it is easy to define new types.

Humans like to use the *decimal number* system for representing numbers. Decimal numbers are *base 10*, which means that a value is represented as two sequences of decimal digits separated by a *decimal point*, where each *digit* d has a position and a value $d \in \{0, 1, 2, \dots, 9\}$. The part before the decimal point is called the *whole part* and the part after is called the *fractional part* of the number. An *integer* is a number with only a whole part and neither a decimal point nor a fractional part. As an example 35.7 is a decimal number, whose value is $3 \cdot 10^1 + 5 \cdot 10^0 + 7 \cdot 10^{-1}$, and 128 is an integer, whose value is $1 \cdot 10^2 + 2 \cdot 10^1 + 8 \cdot 10^0$. In F#, a decimal number is called a *floating point number*. Floating point numbers may alternatively be given using *scientific notation*, such as 3.5e-4 and 4e2, where the e-notation is translated to a value as $3.5e-4 = 3.5 \cdot 10^{-4} = 0.00035$, and $4e2 = 4 \cdot 10^2 = 400$.

The basic unit of information in almost all computers is the binary digit or *bit* for short. Internally, programs and data are all represented as bits, hence F# has a strong support for binary numbers. A *binary number* consists of a sequence of binary digits separated by a decimal point, where each digit can have values $b \in \{0, 1\}$, and the base is 2. E.g., the binary number $101.01_2 = 1 \cdot 2^2 + 0 \cdot 2^1 + 1 \cdot 2^0 + 0 \cdot 2^{-1} + 1 \cdot 2^{-2} = 5.25$. Subscripts are often used to indicate the base of a number, e.g., 101.01_2 and 101.01_{10} are different numbers. Since base 10 is so common, the subscript for base 10 numbers is often omitted.

Character	Escape sequence	Description
BS	\b	Backspace
LF	\n	Line feed
CR	\r	Carriage return
HT	\t	Horizontal tabulation
\	\\	Backslash
"	\"	Quotation mark
'	\'	Apostrophe
BEL	\a	Bell
FF	\f	Form feed
VT	\v	Vertical tabulation
	\uXXXX, \UXXXXXXXX, \DDD	Unicode character ('X' is any hexadecimal digit, and 'D' is any decimal digit)

Table 5.2.: Escape characters. The escapecode \DDD is sometimes called a tricode.

Binary numbers are closely related to *octal* and *hexadecimal numbers*. Octals uses 8 as basis and hexadecimals use 16 as basis. Each octal digit can be represented by exactly three bits, and each hexadecimal digit can be represented by exactly four bits. The hexadecimal digits use 0–9 to represent the values 0–9 and a–f in lower or alternatively upper case to represent the values 10–15. Thus, Octals and hexadecimals conveniently serve as shorthand for the much longer binary representation. As examples, the octal number 37_8 is $3 \cdot 8^1 + 7 \cdot 8^0 = 31$, and the hexadecimal number $f3_{16}$ is $15 \cdot 16^1 + 3 \cdot 16^0 = 243$.

To denote integers in bases different than 10, F# uses the prefix '0b' for binary, '0o' for octal, and '0x' for hexadecimal numbers. For example, the value 367_{10} may be written as an integer 367, as a binary number 0b101101111, as a octal number 0o557, and as a hexadecimal number 0x16f. In F#, the character sequences 0b12 and ff are not recognized as numbers.

A *character* is a *Unicode code point*, and character literals are enclosed in single quotation marks. Appendix C.3 contains more details on code points. The character type in F# is denoted *char*. Examples of characters are 'a', 'D', '3', and examples of non-characters are '23' and 'abc'. Some characters, such as the tabulation character, do not have a visual representation. These can still be represented as a character using *escape sequences*. A character escape sequence starts with “\” followed by letter for simple escapes such as \t for tabulation and \n for newline. Escape sequences can also be a numerical representation of a code point, and three versions exist: The trigraph \DDD, where D is a decimal digit, is used to specify the first 256 code points, the hexadecimal escape codes \uXXXX, where X is a hexadecimal digit, is used to specify the first 65536 code points, and \UXXXXXXXX is used to specify any of the approximately $4.3 \cdot 10^9$ possible code points. All escape sequences are shown in Table 5.2. Examples of char representations of the letter 'a' are: 'a', '\097', '\u0061', '\U00000061'.

A *string* is a sequence of characters enclosed in double quotation marks. Examples are "a", "this is a string", and "-&\@". Note that the string "a" and the character 'a' are not the same. Some strings are so common that they are given special names: One or more spaces " " is called *whitespace*, and both "\n" and "\r\n" are called *newline*. The escape-character “\” may be used to break a line in two. This and other examples are shown in Listing 5.3.

Listing 5.3: Examples of string literals.

```

1  > "abcde";;
2  val it : string = "abcde"
3
4  > "abc
5  -   de";;
6  val it : string = "abc
7  de"
8
9  > "abc\
10 -   de";;
11 val it : string = "abcde"
12
13 > "abc\nde";;
14 val it : string = "abc
15 de"

```

Note that the response from `fsharp` is shown in double quotation marks, but this is not part of the string.

F# supports *literal types*, where the type of a literal is indicated as a prefix or suffix as `literal type` shown in Table 5.3.

The literal type is closely connected to how the values are represented internally. For example, a value of type `int32` use 32 bits and can be both positive and negative, while a `uint32` value also use 32 bits, but is unsigned. A `byte` is an 8-bit number, and `sbyte` is a signed 8-bit number. Values of type `float` use 64 bits, while `float32` only uses 32 bits. The number of bits used to represent numbers directly relates to the range and precision these types can represent. This is summarized in Table 5.1 and discussed in more detail in Appendix B. String literals may be *verbatim* by the `@`-notation or triple double quotation marks, meaning that the escape sequences are not converted to their code point. The two types of string verbatim treat quotation marks differently, as illustrated in the table. Further examples are shown in Listing 5.4.

23 val it : string = "abc\nde"

```

5. Using F# as a Calculator

Many basic types are compatible, and the type of a literal may be changed by *typecasting*. An example of casting to a `float` is shown in Listing 5.5.

Listing 5.5: Casting an integer to a floating point number.

```
1 > float 3;;  
2 val it : float = 3.0
```

When `float` is given an argument, then it acts as a function rather than a type, and for the integer 3 it returns the floating point number 3.0. For more on functions see Chapter 6. Boolean values are often treated as the integer values 0 and 1, but no short-hand function names exist for their conversions. Instead, use functions from the `System.Convert` family of functions, as demonstrated in Listing 5.6.

Listing 5.6: Casting booleans.

```
1 > System.Convert.ToBoolean 1;;  
2 val it : bool = true  
3  
4 > System.Convert.ToBoolean 0;;  
5 val it : bool = false  
6  
7 > System.Convert.ToInt32 true;;  
8 val it : int = 1  
9  
10 > System.Convert.ToInt32 false;;  
11 val it : int = 0
```

Here `System.Convert.ToBoolean` is the identifier of a function `ToBoolean`, which is a *member* of the *class* `Convert` that is included in the *namespace* `System`. Namespaces, classes, and members will be discussed in Chapter 9.

- member
- class
- namespace

Typecasting is often a destructive operation, e.g., typecasting a `float` to `int` removes the fractional part without rounding as shown in Listing 5.7.

Listing 5.7: Fractional part is removed by downcasting.

```
1 > int 357.6;;  
2 val it : int = 357
```

Here we typecasted to a lesser type, in the sense that the set of integers is a subset of floating point numbers, and this is called *downcasting*. The opposite is called *upcasting* and is often non-destructive, as Listing 5.5 showed. Since floating point numbers are a superset of integers, the value is retained. As a side note, *rounding* a number $y.x$, where y is the *whole part* and x is the *fractional part*, is the operation of mapping numbers in the interval $y.x \in [y.0, y.5)$ to y , and those in $y.x \in [y.5, y + 1)$ to $y + 1$. This can be performed by downcasting, as shown in Listing 5.8.

- downcasting
- upcasting
- rounding
- whole part
- fractional part

Listing 5.8: Rounding by modified downcasting.

```
1 > int (357.6 + 0.5);;
2 val it : int = 358
```

I.e., $357.6 + 0.5 = 358.1$ and removing the fractional part by downcasting results in 358, which is the correct answer.

5.2. Operators on Basic Types

Expressions are the basic building block of all F# programs, and this section will discuss operator expressions on basic types. A typical calculation, such used in Listing 5.8, is

$$\underbrace{357.6}_{\text{operand}} \quad \underbrace{+}_{\text{operator}} \quad \underbrace{0.5}_{\text{operand}} \quad (5.1)$$

is an example of an arithmetic *expression*, and the above expression consists of two *operands* and an *operator*. Since this operator takes two operands, it is called a *binary operator*. The expression is written using *infix notation*, since the operands appear on each side of the operator.

In order to discuss general programming structures, we will use a simplified language to describe valid syntactical structures. In this simplified language, the syntax of basic binary operators is shown in the following.

Listing 5.9: Syntax for a binary expression.

```
1 <expr><op><expr>
```

Here **<expr>** is any expression supplied by the programmer, and **<op>** is a binary infix operator. F# supports a range of arithmetic binary infix operators on its built-in types, such as addition, subtraction, multiplication, division, and exponentiation, using the “+”, “-”, “*”, “/”, “**” lexemes, respectively. Not all operators are defined for all types, e.g., addition is defined for integer and float types as well as for characters and strings, but multiplication is only defined for integer and floating-point types. A complete list of built-in operators on basic types is shown in Table E.1 and E.2, and a range of mathematical functions is shown in Table E.3. Note that expressions can themselves be arguments to expressions, and thus, $4+5+6$ is also a legal statement. This is called *recursion*, which means that a rule or a function is used by the rule or function itself in its definition. See Chapter 13 for more on recursive functions.

Unary operators take only one argument and have the syntax:

Listing 5.10: A unary expressions.

```
1 <op><expr>
```

An example of a unary operator is -3 , where $-$ here is used to negate a positive integer. Since the operator appears before the operand, it is a *prefix operator*.

Table 5.4.: Some common operators, their precedence, and their associativity. Rows are ordered from highest to lowest precedences, such that `<expr> * <expr>` has higher precedence than `<expr> + <expr>`. Operators in the same row have the same precedence. Full table is given in Table E.5.

The concept of *precedence* is an important concept in arithmetic expressions.¹ If parentheses are omitted in Listing 5.8, then F# will interpret the expression as `(int 357.6) + 0.5`, which is erroneous since the addition of an integer with a float is undefined. This is an example of precedence, i.e., function evaluation takes precedence over addition which means that function evaluation is performed first and addition second. Consider the arithmetic expression shown in Listing 5.11.

Listing 5.11: A simple arithmetic expression.

```

1  > 3 + 4 * 5;;
2  val it : int = 23

```

Here, the addition and multiplication functions are shown in infix notation with the *operator* lexemes “+” and “*”. To arrive at the resulting value 23, F# has to decide in which order to perform the calculation. There are 2 possible orders, `3 + (4 * 5)` and `(3 + 4) * 5` that gives different results. For integer arithmetic, the correct order is, of course, multiplication before addition, and we say that multiplication takes *precedence* over addition. Every atomic operation that F# can perform is ordered in terms of its precedence, and for some common built-in operators shown in Table 5.4, the precedence is shown by the order they are given in the table.

¹Jon: minor comment on indexing and slice-ranges.

5. Using F# as a Calculator

a	b	a && b	a b	not a
false	false	false	false	true
false	true	false	true	true
true	false	false	true	false
true	true	true	true	false

Table 5.5.: Truth table for boolean 'and', 'or', and 'not' operators. Value 0 is false and 1 is true.

Associativity describes the order in which calculations are performed for binary operators of the same precedence. Some operator's associativity are given in Table 5.4. In the table we see that “*” is left associative, which means that $3.0 * 4.0 * 5.0$ is evaluated as $(3.0 * 4.0) * 5.0$. Conversely, ****** is right associative, so $4.0**3.0**2.0$ is evaluated as $4.0**(3.0**2.0)$. For some operators, like multiplication, association matters little, e.g., $4 * 3 * 2 = 4 * (3 * 2) = (4 * 3) * 2$, and for other operators, like exponentiation, association makes a huge difference, e.g., $4^{(3^2)} \neq (4^3)^2$. Examples of this is shown in Listing 5.12.

Listing 5.12: Precedence rules define implicit parentheses.

```

1 > 4.0 * 3.0 * 2.0;;
2 val it : float = 24.0
3
4 > (4.0 * 3.0) * 2.0;;
5 val it : float = 24.0
6
7 > 4.0 * (3.0 * 2.0);;
8 val it : float = 24.0

Advice

Whenever in doubt of association or any other basic semantic rules, it is a good idea to use parentheses. It is also a good idea to test your understanding of the syntax and semantic rules by making a simple script.

5.3. Boolean Arithmetic

Boolean arithmetic is the basis of almost all computers and particularly important for controlling program flow, which will be discussed in Chapter 8. Boolean values are one of 2 possible values, true or false, which is also sometimes written as 1 and 0. Basic operations on Boolean values are 'and', 'or', and 'not', which in F# are written respectively as the binary operators **&&**, **||**, and the function **not**. Since the domain of Boolean values is so small, all possible combination of input on these values can be written on the tabular form, known as a *truth table*, and the truth tables for the basic Boolean operators and functions are shown in Table 5.5. A good mnemonic for remembering the result of the 'and' and 'or'

· and
· or
· not
· truth table

operators is to use 1 for true, 0 for false, multiplication for the Boolean 'and' operator, and addition for the Boolean 'or' operator, e.g., true and false in this mnemonic translates to $1 \cdot 0 = 0$, and the result translates back to the Boolean value false. In F#, the truth table for the basic Boolean operators can be produced by a program, as shown in Listing 5.13.

Listing 5.13: Boolean operators and truth tables.

```

1 > printfn "a b a*b a+b not a"
2 - printfn "%A %A %A %A %A"
3 -   false false (false && false) (false || false) (not false)
4 - printfn "%A %A %A %A %A"
5 -   false true (false && true) (false || true) (not false)
6 - printfn "%A %A %A %A %A"
7 -   true false (true && false) (true || false) (not true)
8 - printfn "%A %A %A %A %A"
9 -   true true (true && true) (true || true) (not true);;
10 a b a*b a+b not a
11 false false false false true
12 false true false true true
13 true false false true false
14 true true true true false
15 val it : unit = ()

```

Here, we used the `printfn` function to present the results of many expressions on something that resembles a tabular form. The spacing produced using the `printfn` function is not elegant, and in Section 6.5 we will discuss better options for producing more beautiful output. Notice that the arguments for `printfn` was given on the next line with indentation. The indentation is an important part of telling F# which part of what you write belong together. This is an example of the so-called lightweight syntax. Generally, F# ignores newlines and whitespaces except when using the lightweight syntax. The difference between verbose and lightweight syntax is discussed in Chapter 6.

5.4. Integer Arithmetic

The set of integers is infinitely large, but since all computers have limited resources, it is not possible to represent it in its entirety. The various integer types listed in Table 5.1 are finite subsets reduced by limiting their ranges. An in-depth description of integer implementation can be found in Appendix B. The type `int` is the most common type.

Table E.1–E.3 give examples of operators and functions pre-defined for integer types. Notice that fewer functions are available for integers than for floating point numbers. For most addition, subtraction, multiplication, and negation, the result is straightforward. However, performing arithmetic operations on integers requires extra care, since the result may cause *overflow* and *underflow*. For example, an `sbyte` is specified using the “y”-literal and can hold values $[-128 \dots 127]$. This causes problems in the example in Listing 5.14.

· overflow
· underflow

Listing 5.14: Adding integers may cause overflow.

```

1 > 100y;;
2 val it : sbyte = 100y
3
4 > 30y;;
5 val it : sbyte = 30y
6
7 > 100y + 30y;;
8 val it : sbyte = -126y

```

Here $100 + 30 = 130$, which is larger than the biggest `sbyte`, and the result is an overflow. Similarly, we get an underflow, when the arithmetic result falls below the smallest value storable in an `sbyte`, as demonstrated in Listing 5.15.

Listing 5.15: Subtracting integers may cause underflow.

```

1 > -100y - 30y;;
2 val it : sbyte = 126y

```

I.e., we were expecting a negative number but got a positive number instead.

The overflow error in Listing 5.14 can be understood in terms of the binary representation of integers: In binary, $130 = 10000010_2$, and this binary pattern is interpreted differently as `byte` and `sbyte`, see Listing 5.16.

Listing 5.16: The leftmost bit is interpreted differently for signed and unsigned integers, which gives rise to potential overflow errors.

```

1 > 0b10000010uy;;
2 val it : byte = 130uy
3
4 > 0b10000010y;;
5 val it : sbyte = -126y

```

That is, for signed bytes, the left-most bit is used to represent the sign, and since the addition of $100 = 01100100_2$ and $30 = 00011110_2$ is $130 = 10000010_2$, which causes the left-most bit to be used, this is wrongly interpreted as a negative number when stored in an `sbyte`. Similar arguments can be made explaining underflows.

The `/` operator discards the fractional part after division, and the *integer remainder* operator `%` calculates the remainder after integer division, as demonstrated in Listing 5.17.

Listing 5.17: Integer division and remainder operators.

```

1 > 7 / 3;;
2 val it : int = 2
3
4 > 7 % 3;;
5 val it : int = 1

```

5. Using F# as a Calculator

Together, the integer division and remainder can form a lossless representation of the original number, see Listing 5.18.

Listing 5.18: Integer division and remainder is a lossless representation of an integer, compare with Listing 5.17.

```
1 > (7 / 3) * 3;;
2 val it : int = 6
3
4 > (7 / 3) * 3 + (7 % 3);;
5 val it : int = 7
```

Here we see that integer division of 7 by 3 followed by multiplication by 3 is less than 7, and that the difference is $7 \% 3$.

Notice that neither overflow nor underflow error gave rise to an error message, which is why such bugs are difficult to find. Dividing any non-zero number by 0 is infinite, which is also outside the domain of any of the integer types, but in this case, F# casts an *exception*, as shown in Listing 5.19.

Listing 5.19: Integer division by zero causes an exception runtime error.

```
1 > 3/0;;
2 System.DivideByZeroException: Attempted to divide by zero.

The output looks daunting at first sight, but the first and last lines of the error message are the most important parts, which tell us what exception was cast and why the program stopped. The middle contains technical details concerning which part of the program caused the error and can be ignored for the time being. Exceptions are a type of *runtime error*, and are discussed in Chapter 18.

Integer exponentiation is not defined as an operator but is available as the built-in function `pown`. This function is demonstrated in Listing 5.20 for calculating 2^5 .

Listing 5.20: Integer exponent function.

```
1 > pown 2 5;;

For binary arithmetic on integers, the following operators are available: `<leftExpr> <<< <rightExpr>`, which shifts the bit pattern of `<leftExpr>` `<rightExpr>` positions to the left

5.5. Floating Point Arithmetic

Like integers, the set of reals is also infinitely large, hence, floating point types are finite subsets reduced by sampling the space of reals. An in-depth description of floating point implementations can be found in Appendix B. The type `float` is the most common type.

Table E.1–E.3 give examples of operators and functions pre-defined for floating point types. Note that the remainder operator for floats calculates the remainder after division and discards the fractional part, see Listing 5.21.

Listing 5.21: Floating point division and remainder operators.

```
1 > 7.0 / 2.5;;
2 val it : float = 2.8
3
4 > 7.0 % 2.5;;
5 val it : float = 2.0
```

The remainder for floating point numbers can be fractional, but division, discarding fractional part, and the remainder is still a lossless representation of the original number, as demonstrated in Listing 5.22.

Listing 5.22: Floating point division, downcasting, and remainder is a lossless representation of a number.

```
1 > float (int (7.0 / 2.5));;
2 val it : float = 2.0
3
4 > (float (int (7.0 / 2.5))) * 2.5;;
5 val it : float = 5.0
6
7 > (float (int (7.0 / 2.5))) * 2.5 + 7.0 % 2.5;;
8 val it : float = 7.0
```

Arithmetic using `float` will not cause over- and underflow problems, since the IEEE 754 standard includes the special numbers $\pm\infty$ and NaN. As shown in Listing 5.23, no exception is thrown.

Listing 5.23: Floating point numbers include infinity and Not-a-Number.

```
1 > 1.0/0.0;;
2 val it : float = infinity
3
4 > 0.0/0.0;;
5 val it : float = nan
```

However, the `float` type has limited precision, since there is only a finite number of numbers that can be stored in a float. E.g., addition and subtraction can give surprising results, as demonstrated in Listing 5.24.

Listing 5.24: Floating point arithmetic has finite precision.

```
1 > 357.8 + 0.1 - 357.9;;
2 val it : float = 5.684341886e-14
```

That is, addition and subtraction associates to the left, hence the expression is interpreted as $(357.8 + 0.1) - 357.9$ and we see that we do not get the expected 0. The reason is that the calculation is done stepwise, and in the process, the numbers are represented using the imprecise floating point standard. Thus, $357.8 + 0.1$ is represented as a number close to but not identical to what 357.9 is represented as, and thus, when subtracting these two representations, we get a very small nonzero number. Such errors tend to accumulate, and comparing the result of expressions of floating point values should, therefore, be treated with care. Thus, **equivalence of two floating point expressions should only be considered up to sufficient precision, e.g., comparing $357.8 + 0.1$ and 357.9 up to $1e-10$ precision should be tested as, `abs ((357.8 + 0.1) - 357.9) < 1e-10`.** Advice

5.6. Char and String Arithmetic

Addition is the only operator defined for characters. Nevertheless, character arithmetic is often done by casting to an integer. A typical example is the conversion of character case, e.g., to convert the lowercase character 'z' to uppercase. Here, we use the *ASCIIbetical order*, add the difference between any Basic Latin Block letters in upper- and lowercase as *· ASCIIbetical order integers*, and cast back to `char`, see Listing 5.25.

Listing 5.25: Converting case by casting and integer arithmetic.

```
1 > char (int 'z' - int 'a' + int 'A');;
2 val it : char = 'Z'
```

I.e., the code point difference between upper and lower case for any alphabetical character 'a' to 'z' is constant, hence we can change case by adding or subtracting the difference between any corresponding character. Unfortunately, this does not generalize to characters from other languages.

5. Using F# as a Calculator

A large collection of operators and functions exist for `string`. The simplest is concatenation using the “+” operator, as demonstrated in Listing 5.26.

Listing 5.26: Example of string concatenation.

```
1 > "hello" + " " + "world";;
2 val it : string = "hello world"
```

Characters and strings cannot be concatenated, which is why the above example used the string of a space " " instead of the space character ' '. The characters of a string may be indexed as using the `.[]` notation. This is demonstrated in Listing 5.27.

Listing 5.27: String indexing using square brackets.

```
1 > "abcdefg".[0];;
2 val it : char = 'a'
3
4 > "abcdefg".[3];;
5 val it : char = 'd'
6
7 > "abcdefg".[3..];;
8 val it : string = "defg"
9
10 > "abcdefg".[..3];;
11 val it : string = "abcd"
12
13 > "abcdefg".[1..3];;
14 val it : string = "bcd"
15
16 > "abcdefg".[*];;
17 val it : string = "abcdefg"
```

Notice that the first character has index 0, and to get the last character in a string, we use the string’s `length` property. This is done as shown in Listing 5.28.

Listing 5.28: String length attribute and string indexing.

```
1 > "abcdefg".Length;;
2 val it : int = 7
3
4 > "abcdefg".[7-1];;
5 val it : char = 'g'
```

Since index counting starts at 0, and since the string length is 7, the index of the last character is 6. There is a long list of built-in functions in `System.String` for working with strings, some of which will be discussed in Section 11.1.

The *dot notation* is an example of Structured programming, where technically speaking, the string `"abcdefg"` is an immutable *object* of *class* `string`, `[]` is an object *method*, and `Length` is a property. For more on objects, classes, and methods, see Chapter 20.

- dot notation
- object
- class
- method

Strings are compared letter by letter. For two strings to be equal, they must have the same length and all the letters must be identical. E.g., `"abs" = "absalon"` is false, while

"abs" = "abs" is true. The "<>" operator is the boolean negation of the "=" operator, e.g., "abs" <> "absalon" is true, while "abs" <> "abs" is false. For the "<", "<=", ">", and ">=" operators, the strings are ordered alphabetically, such that "abs" < "absalon" && "absalon" < "milk" is true, that is, the "<" operator on two strings is true if the left operand should come before the right when sorting alphabetically. The algorithm for deciding the boolean value of leftOp < rightOp is as follows: we start by examining the first character, and if leftOp.[0] and rightOp.[0] are different, then leftOp < rightOp is equal to leftOp.[0] < rightOp.[0]. E.g., "milk" < "abs" is the same as 'm' < 'a', which is false, since the letter 'm' does not come before the letter 'a' in the alphabet, or more precisely, the codepoint of 'm' is not less than the codepoint of 'a'. If leftOp.[0] and rightOp.[0] are equal, then we move on to the next letter and repeat the investigation, e.g., "abe" < "abs" is true, since "ab" = "ab" is true and 'e' < 's' is true. If we reach the end of either of the two strings, then the shorter word is smaller than the longer word, e.g., "abs" < "absalon" is true, while "abs" < "abs" is false. The "<=", ">", and ">=" operators are defined in a similar manner.

5.7. Programming Intermezzo: Hand Conversion Between Decimal and Binary Numbers

Conversion of integers between decimal and binary form is a key concept one must grasp in order to understand some of the basic properties of calculations on the computer. Converting from binary to decimal is straightforward if using the power-of-two algorithm, i.e., given a sequence of $n + 1$ binary digits b_i written as $b_n b_{n-1} \dots b_0$, and where b_n and b_0 are the most and least significant bits respectively, then the decimal value is calculated as,

$$v = \sum_{i=0}^n b_i 2^i \quad (5.2)$$

For example, $10011_2 = 1 + 2 + 16 = 19$. Converting from decimal to binary is a little more complex, but a simple divide-by-two algorithm exists. The key to understanding the divide-by-two algorithm is to realize that dividing a number by two is equivalent to shifting its binary representation one position to the right. E.g., $10 = 1010_2$ and $10/2 = 5 = 101_2$. Odd numbers have $b_0 = 1$, e.g., $11_{10} = 1011_2$ and $11_{10}/2 = 5.5 = 101.1_2$. Hence, if we divide any number by two and get a non-integer number, then its least significant bit was 1. Another way to express this is to say that the least significant bit is the remainder after integer division by two. Sequential application of this idea leads directly to the divide-by-two algorithm. E.g., if we were to convert the number 11_{10} in decimal form to binary form, we would perform the following steps:

Here we used div and rem to signify the integer division and remainder operators. The algorithm stops when the result of integer division is zero. Reading off the remainder

5. Using F# as a Calculator

from below and up, we find the sequence 1011_2 , which is the binary form of the decimal number 11_{10} . Using the interactive mode, we can perform the same calculation, as shown in Listing 5.29.

Listing 5.29: Converting the number 11_{10} to binary form.

```
1 > printfn "(%d, %d)" (11 / 2) (11 % 2);;
2 (5, 1)
3 val it : unit = ()
4 > printfn "(%d, %d)" (5 / 2) (5 % 2);;
5 (2, 1)
6 val it : unit = ()
7 > printfn "(%d, %d)" (2 / 2) (2 % 2);;
8 (1, 0)
9 val it : unit = ()
10 > printfn "(%d, %d)" (1 / 2) (1 % 2);;
11 (0, 1)
12 val it : unit = ()
```

Thus, by reading the second integer-response from `printfn` from below and up, we again obtain the binary form of 11_{10} to be 1011_2 . For integers with a fractional part, the divide-by-two algorithm may be used on the whole part, while multiply-by-two may be used in a similar manner on the fractional part.

6 | Values and Functions

In this chapter, we will see how we can bind expressions to identifiers either as new constants, functions, or operators, how this saves time when building large programs, and how this makes programs easier to read and debug. As an example, consider the following problem,

Problem 6.1

For given set constants a , b , and c , solve for x in

$$ax^2 + bx + c = 0 \tag{6.1}$$

To solve for x we use the quadratic formula from elementary algebra,

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}, \tag{6.2}$$

which gives the general solution for any values of the coefficients. Here, we will assume a positive discriminant, $b^2 - 4ac > 0$. In order to write a program where the code may be reused later, we define a function `discriminant : float -> float -> float -> float`, that is, a function that takes 3 arguments, `a`, `b`, and `c`, and calculates the discriminant. Likewise, we will define `positiveSolution : float -> float -> float -> float` and `negativeSolution : float -> float -> float -> float`, that also take the polynomial's coefficients as arguments and calculate the solution corresponding to choosing the positive and negative sign for \pm in the equation. Details on function definition is given in Section 6.2. Our solution thus looks like Listing 6.1.

Listing 6.1 identifiersExample.fsx:

Finding roots for quadratic equations using function name binding.

```

1  let discriminant a b c = b ** 2.0 - 4.0 * a * c
2  let positiveSolution a b c = (-b + sqrt (discriminant a b c))
   / (2.0 * a)
3  let negativeSolution a b c = (-b - sqrt (discriminant a b c))
   / (2.0 * a)
4
5  let a = 1.0
6  let b = 0.0
7  let c = -1.0
8  let d = discriminant a b c
9  let xp = positiveSolution a b c
10 let xn = negativeSolution a b c
11 do printfn "0 = %A * x ** 2.0 + %A * x + %A" a b c
12 do printfn "  has discriminant %A and solutions %A and %A" d
   xn xp

```

```

1  $ fsharp --nologo identifiersExample.fsx && mono
   identifiersExample.exe
2  0 = 1.0 * x ** 2.0 + 0.0 * x + -1.0
3  has discriminant 4.0 and solutions -1.0 and 1.0

```

Here, we have further defined names of values `a`, `b`, and `c` which are used as inputs to our functions, and the results of function application are bound to the names `d`, `xn`, and `xp`. The names of functions and values given here are examples of identifiers, and with these, we may reuse the quadratic formulas and calculated values later, while avoiding possible typing mistakes and reducing the amount of code which needs to be debugged.

The use of identifiers is central in programming. For F#, not to be confused with built-in functionality, identifiers must follow a specific set of rules:

· identifier

Identifier

- Identifiers are used as names for values, functions, types etc.
- They must start with a Unicode letter or underscore '`_`', but can be followed by zero or more of letters, digits, and a range of special characters except for SP, LF, and CR (space, line feed, and carriage return). See Appendix C.3 for more on codepoints that represents letters.
- They can also be a sequence of identifiers separated by a period.
- They cannot be keywords, see Table 6.1.

Examples of identifiers are: `a`, `theCharacter9`, `Next_Word`, `_tok`, and `f.sharp.rocks`. Since programmers often work in multilingual environment dominated by the English language it is advisable to **restrict identifiers to use letters from the English alphabet, numbers, period, and '`_`'**. However, the number of possible identifiers is enormous. The full definition refers to the Unicode general categories described in Appendix C.3, and there are currently 19.345 possible Unicode code points in the letter category and 2.245 possible Unicode code points in the special character category.

Identifiers may be used to carry information about their intended content and use, and careful selection of identifiers can aid programmers to communicate thoughts about the code. Thus, identifiers are often a word or several concatenated words conveying some relevant meaning. For example, in the function definition `let discriminant a b c = b ** 2.0 - 4.0 * a * c`, the function identifier has been chosen to be `discriminant`. F# places no special significance to the word 'discriminant', and the program would work exactly the same had the function been called `let f a b c = b ** 2.0 - 4.0 * a * c`. However, to programmers, the word 'discriminant' informs us of the intended role of the function and thus is much preferred. This is a general principle: **identifier names should be chosen to reflect their semantic value.** The arguments `a`, `b`, and `c` are short, but adheres to a textbook tradition of elementary algebra. Again, we might as well have used, `let discriminant c a b = a ** 2.0 - 4.0 * c * b`, which is semantically identical to the original expression, but due to tradition, this would confuse most readers of the code. Thus, **identifier names should be chosen consistently with the readers' traditions.** Finally, identifiers are often concatenations of words, as `positiveSolution` in Listing 6.1. Concatenations can be difficult to read. Without the capitalization of the second word, we would have had `positivesolution`. This is readable at most times, but takes longer time to understand in general. Typical solutions are to use a separator, such as `positive_solution`, *lower camel case* also known as *mixed case* as in the example `positiveSolution`, and *upper camel case* also known as *pascal case* as `PositiveSolution`. In this book, we use lower camel case except where F# requires a capital first letter. Again, the choice does not influence what a program does, only how readable it is to a fellow programmer. The important part is that **identifier names consisting of concatenated words are often preferred over names with few character, and concatenation should be emphasized, e.g., by camel casing.** Choosing the length of identifier names is a balancing act, since when working with large programs, very long identifier names can be tiresome to write, and a common practice is that the length of identifier names is proportional to the complexity of the program. I.e., complex programs use long names, simple programs use short names. What is complex and what is simple is naturally in the eye of the beholder, but when you program, remember that a future reader of the program most likely has not had time to work with the problem as long as the programmer, thus

Another key concept in F# is expressions. An expression can be a mathematical expression, such as $3 * 5$, a function application, such as $f3$, and many other things. Central in this chapter is the binding of values and functions to identifiers, which is done with the keyword `let`, e.g., `let a = 1.0`.

Expressions are the main workhorse of F# and have an enormous variety in how they may be written. We will in this book gradually work through some of the more important facets.

· expression

Expressions

- An Expression is a computation such as $3 * 5$.
- They can be value bindings between identifiers and expressions that evaluate to a value or a function, see Sections 6.1 and 6.2.
- They can be `do`-bindings that produce side-effects and whose result are ignored, see Section 6.2
- They can be assignments to variables, see Section 6.1.
- They can be a sequence of expressions separated with the “;” lexeme.
- They can be annotated with a type by using the “:” lexeme.

· ;

· :

Before we begin a deeper discussion on bindings, note that F# adheres to two different syntaxes: *verbose* and *lightweight*. In the verbose syntax, newlines and whitespaces are generally ignored, while in lightweight syntax, certain keywords and lexemes may be replaced by newlines and whitespaces. The lightweight syntax is the most common, but the syntaxes may be mixed, and we will highlight the options, when relevant.

6.1. Value Bindings

Binding identifiers to literals, or expressions that are evaluated to be values, is called *value-binding*, and examples are `let a = 3.0` and `let b = cos 0.9`. Value bindings have the following syntax:

· value-binding

Listing 6.2: Value binding expression.

```
1 let <valueIdent> = <bodyExpr> [in <expr>]
```

The `let` keyword binds a value-identifier `<valueIdent>` with an expression `<bodyExpr>` that evaluates to a value. The following square bracket notation `[]` means that the enclosed is optional, and F# is able to identify whether or not the optional part is used by whether or not the `in` keyword is present in the binding expression. If the `in` keyword is used, then the value-identifier is a local definition in the following `<expr>` expression but in the following lines. For lightweight syntax, the `in` keyword is replaced with a newline, and the binding is valid in the following lines at the level of scope of the value-binding, or deeper, *lexically*.

· let

· in

· lexically

The value identifier annotated with a type by using the “:” lexeme followed by the name of a type, e.g., `int`. The “_” lexeme may be used as a value-identifier. This lexeme is called the *wildcard* pattern, and for value-bindings it means that `<bodyExpr>` is evaluated, but the result is discarded. See Chapter 15 for more details on patterns.

For example, letting the identifier `p` be bound to the value `2.0` and using it in an expression is done as shown in Listing 6.3.

Listing 6.3 `letValue.fsx`:

The identifier `p` is used in the expression following the `in` keyword.

```
1 let p = 2.0 in do printfn "%A" (3.0 ** p)

1 $ fsharp --nologo letValue.fsx && mono letValue.exe
2 9.0
```

F# will ignore most newlines between lexemes, i.e., the above is equivalent to writing as shown in Listing 6.4.

Listing 6.4 `letValueLF.fsx`:

Newlines after `in` make the program easier to read.

```
1 let p = 2.0 in
2 do printfn "%A" (3.0 ** p)

1 $ fsharp --nologo letValueLF.fsx && mono letValueLF.exe
2 9.0
```

F# also allows for an alternative notation called *lightweight syntax*, where e.g., the `in` keyword is replaced with a newline, and the expression starts on the next line at the same column as `let` starts in, i.e., the above is equivalent to Listing 6.5.

Listing 6.5 `letValueLightWeight.fsx`:

Lightweight syntax does not require the `in` keyword, but the expression must be aligned with the `let` keyword.

```
1 let p = 2.0
2 do printfn "%A" (3.0 ** p)

1 $ fsharp --nologo letValueLightWeight.fsx
2 $ mono letValueLightWeight.exe
3 9.0
```

The same expression in interactive mode will also show with the inferred types, as shown in Listing 6.6.

Listing 6.6: Interactive mode also outputs inferred types.

```

1 > let p = 2.0
2 - do printfn "%A" (3.0 ** p);;
3 9.0
4 val p : float = 2.0
5 val it : unit = ()

```

By the `val` keyword in the line `val p : float = 2.0`, we see that `p` is inferred to be of type `float` and bound to the value `2.0`. The inference is based on the type of the right-hand-side which is `float`. Identifiers may be defined to have a type using the “:” lexeme, but the types on the left-hand-side and right-hand-side of the “=” lexeme must be identical. Mixing types gives an error, as shown in Listing 6.7.

**Listing 6.7 letValueTypeError.fsx:
Binding error due to type mismatch.**

```

1 let p : float = 3
2 do printfn "%A" (3.0 ** p)

```

```

1 $ fsharp -nologo letValueTypeError.fsx && mono
   letValueTypeError.exe
2
3 letValueTypeError.fsx(1,17): error FS0001: This expression was
   expected to have type
4     'float'
5 but here has type
6     'int'

```

Here, the left-hand-side is defined to be an identifier of type `float`, while the right-hand-side is a literal of type `integer`.

An expression can be a sequence of expressions separated by the lexeme “;”, see Listing 6.8.

**Listing 6.8 letValueSequence.fsx:
A value-binding for a sequence of expressions.**

```

1 let p = 2.0 in do printfn "%A" p; do printfn "%A" (3.0 ** p)

```

```

1 $ fsharp -nologo letValueSequence.fsx && mono
   letValueSequence.exe
2 2.0
3 9.0

```

The lightweight syntax automatically inserts the “;” lexeme at newlines, hence using the lightweight syntax, the above is the same as shown in Listing 6.9.

Listing 6.9 `letValueSequenceLightWeight.fsx`:

A value-binding for a sequence using lightweight syntax.

```

1  let p = 2.0
2  do printfn "%A" p
3  do printfn "%A" (3.0 ** p)

```

```

1  $ fsharp --nologo letValueSequenceLightWeight.fsx
2  $ mono letValueSequenceLightWeight.exe
3  2.0
4  9.0

```

A key concept of programming is *scope*. In F#, the scope of a value-binding is lexically. This means that when F# seeks the value bound to a name, it looks left and upward in the program text for its `let`-binding in the present or higher scopes, see Listing 6.10 for an example.

Listing 6.10 `letValueScopeLower.fsx`:

Redefining identifiers is allowed in lower scopes.

```

1  let p = 3 in let p = 4 in do printfn " %A" p;

```

```

1  $ fsharp --nologo letValueScopeLower.fsx && mono
   letValueScopeLower.exe
2  4

```

Some special bindings are mutable, in which case F# uses the dynamic scope, that is, the value of a binding is defined by when it is used. This will be discussed in Section 6.7.

Scopes are given levels, and scopes may be nested, where the nested scope has a level one lower than its parent.¹ F# distinguishes between the top and lower levels, and at the top level in the lightweight syntax, redefining values is not allowed, as shown in Listing 6.11.

Listing 6.11 `letValueScopeLowerError.fsx`:

Redefining identifiers is not allowed in lightweight syntax at top level.

```

1  let p = 3
2  let p = 4
3  do printfn "%A" p;

```

```

1  $ fsharp --nologo -a letValueScopeLowerError.fsx
2
3  letValueScopeLowerError.fsx(2,5): error FS0037: Duplicate
   definition of value 'p'

```

However, using parentheses, we create a *block*, i.e., a *nested scope*, and then redefining is allowed, as demonstrated in Listing 6.12.

¹Jon: Drawings would be good to describe scope

Listing 6.12 `letValueScopeBlockAlternative3.fsx`:

A block may be created using parentheses.

```

1  (
2      let p = 3
3      let p = 4
4      do printfn "%A" p
5  )

```

```

1  $ fsharp --nologo letValueScopeBlockAlternative3.fsx
2  $ mono letValueScopeBlockAlternative3.exe
3
4

```

Nevertheless, **avoid reusing names unless it's in a deeper scope.**

Advice

Inside the block in Listing 6.12 we used indentation, which is good practice, but not required here.

Bindings inside a nested scope are not available outside, as shown in Listing 6.13.

Listing 6.13 `letValueScopeNestedScope.fsx`:

Bindings inside a scope are not available outside.

```

1  let p = 3
2  (
3      let q = 4
4      do printfn "%A" q

6  do printfn "%A %A" p q

```

   constructor 'q' is not defined. Maybe you want one of the
   following:

```

Nesting is a natural part of structuring code, e.g., through function definitions to be discussed in Section 6.2 and flow control structures to be discussed in Chapter 8. Blocking code by nesting is a key concept for making robust code that is easy to use by others, without the user necessarily needing to know the details of the inner workings of a block of code.

Defining blocks is used for controlling the extent of a lexical scope of bindings. For example, adding a second `printfn` statement, as in Listing 6.14, will print the value 4, last bound to the identifier `p`, since F# interprets the above as `let p = 3 in let p = 4 in (printfn "%A" p; printfn "%A" p)`.

Listing 6.14 letValueScopeBlockProblem.fsx:
Overshadowing hides the first binding.

```
1 let p = 3 in let p = 4 in do printfn "%A" p; do printfn "%A" p

-----

1 $ fsharp --nologo letValueScopeBlockProblem.fsx
2 $ mono letValueScopeBlockProblem.exe
3 4
4 4
```

Had we intended to print the two different values of `p`, then we should have created a block as in Listing 6.15.

Listing 6.15 letValueScopeBlock.fsx:
Blocks allow for the return to the previous scope.

```
1 let p = 3 in (let p = 4 in do printfn "%A" p); do printfn "%A"

6.2. Function Bindings

A function is a mapping between an input and output domain. A key advantage of using functions when programming is that they encapsulate code into smaller units, that are easier to debug and may be reused. F# is a functional first programming language and offers a number of alternative methods for specifying parameters, which will be discussed in this section. Binding identifiers to functions follows a syntax similar to value-binding,

Listing 6.16: Function binding expression

```
1 let <funcIdent> <arg> {<arg>} | () = <bodyExpr> [in <expr>]
```

Here `<funcIdent>` is an identifier and is the name of the function, `<arg>` is zero or more identifiers, that bind to the value used when calling the function, and which is to be used in the body of the function, the expression `<bodyExpr>`. The `|` notation denotes a choice, i.e., either that on the left-hand-side or that on the right-hand-side. Thus `let f x = x * x` and `let f () = 3` are valid function bindings, but `let f = 3` would be a value binding, not a function binding. The arguments and the function may be annotated with a type, in which case for arguments we write

Listing 6.17: Function binding expression

```
1  let <funcIdent> (<arg> : <type>) {(<arg> : <type>)} : <type> |
    () : <type> = <bodyExpr> [in <expr>]
```

where `<type>` is a name of an existing type. The argument types are given in parentheses, and the return type is given last.

Functions are a key concept in F#, and in this chapter we will discuss the very basics. Recursive functions will be discussed in Chapter 8 and higher-order functions in Chapter 16.

An example of defining a function and using it in interactive mode is shown in Listing 6.18.

Listing 6.18: An example of a binding of an identifier and a function.

```
1  > let sum (x : float) (y : float) : float = x + y in
2  - let c = sum 357.6 863.4 in
3  - do printfn "%A" c;;
4  1221.0
5  val sum : x:float -> y:float -> float
6  val c : float = 1221.0
7  val it : unit = ()
```

Here we see that the function is interpreted to have the type `val sum : x:float -> y:float -> float`. The “->” lexeme means a mapping between sets, in this case, floats. The function is also a higher order function, to be discussed in detail below, and here it suffices to think of `sum` as a function that takes 2 floats as argument and returns a float.

Not all types need to be declared, just a sufficient number for F# to be able to infer the types for the full statement. For the example, one is sufficient, and we could just have declare the type of the result, as in Listing 6.19.

Listing 6.19 `letFunctionAlterative.fsx`:
Not every type needs to be declared.

```
1  let sum x y : float = x + y
```

Or even just one of the arguments, as in Listing 6.20.

Listing 6.20 `letFunctionAlterative2.fsx`:
Just one type is often enough for F# to infer the rest.

```
1  let sum (x : float) y = x + y
```

In both cases, since the `+` operator is only defined for *operands* of the same type, declaring the type of either arguments or result implies the type of the remainder. As for values, lightweight syntax automatically inserts the keyword `in` and the lexeme “;”, as shown in Listing 6.21.

Listing 6.21 `letFunctionLightWeight.fsx`:
Lightweight syntax for function definitions.

```

1  let sum x y : float = x + y
2  let c = sum 357.6 863.4
3  do printfn "%A" c

-----

1  $ fsharpc --nologo letFunctionLightWeight.fsx
2  $ mono letFunctionLightWeight.exe
3  1221.0

```

Arguments need not always be inferred to types, but may be of the generic type when *type safety* is ensured, as shown in Listing 6.22.

· type safety

Listing 6.22: Type safety implies that a function will work for any type.

```

1  > let second x y = y
2  - let a = second 3 5
3  - do printfn "%A" a
4  - let b = second "horse" 5.0
5  - do printfn "%A" b;;
6  5
7  5.0
8  val second : x:'a -> y:'b -> 'b
9  val a : int = 5
10 val b : float = 5.0
11 val it : unit = ()

```

Here, the function `second` does not use the first argument `x`, which therefore can be of any type, and which F#, therefore, calls `'a`. The type of the second element, `y`, can also be of any type and not necessarily the same as `x`, so it is called `'b`. Finally, the result is the same type as `y`, whatever it is. This is an example of a *generic function*, since it will work on any type.

· generic function

A function may contain a sequence of expressions but must return a value. E.g., the quadratic formula may be written as shown in Listing 6.23.

Listing 6.23 identifiersExampleAdvance.fsx:

A function may contain sequences of expressions.

```

1 let solution a b c sgn =
2     let discriminant a b c =
3         b ** 2.0 - 2.0 * a * c
4     let d = discriminant a b c
5     (-b + sgn * sqrt d) / (2.0 * a)
6
7 let a = 1.0
8 let b = 0.0
9 let c = -1.0
10 let xp = solution a b c +1.0
11 let xn = solution a b c -1.0
12 do printfn "0 = %A * x ** 2.0 + %A * x + %A" a b c
13 do printfn "  has solutions %A and %A" xn xp

```

```

1 $ fsharpc --nologo identifiersExampleAdvance.fsx
2 $ mono identifiersExampleAdvance.exe
3 0 = 1.0 * x ** 2.0 + 0.0 * x + -1.0
4   has solutions -0.7071067812 and 0.7071067812

```

Here, we used the lightweight syntax, where the “=” identifies the start of a nested scope, and F# identifies the scope by indentation. The amount of space used for indentation does not matter, but all lines in the same scope must use the same amount. The scope ends before the first line with the previous indentation or none. Notice how the last expression is not bound to an identifier, but is the result of the function, i.e., in contrast to many other languages, F# does not have an explicit keyword for returning values, but requires a final expression, which will be returned to the caller of the function. Note also that since the function `discriminant` is defined in the nested scope of `solution`, and because the scope ends before `let a = 1.0`, `discriminant` cannot be called outside `solution`.

Lexical scope and function definitions can be a cause of confusion, as the following example · lexical scope in Listing 6.24 shows.²

Listing 6.24 lexicalScopeNFunction.fsx:Lexical scope means that $f(z) = 3x$ and not $4x$ at the time of calling.

```

1 let testScope x =
2     let a = 3.0
3     let f z = a * z
4     let a = 4.0
5     f x
6 do printfn "%A" (testScope 2.0)

```

```

1 $ fsharpc --nologo lexicalScopeNFunction.fsx
2 $ mono lexicalScopeNFunction.exe
3 6.0

```

Here, the value-binding for `a` is redefined after it has been used to define a helper function `f`. So which value of `a` is used when we later apply `f` to an argument? To resolve the

²Jon: Add a drawing or possibly a spell-out of lexical scope here.

confusion, remember that value-binding is lexically defined, i.e., the binding `let f z = a * z` uses the value of `a` as it is defined by the ordering of the lines in the script, not dynamically by when `f` was called. Hence, **think of lexical scope as substitution of an identifier with its value or function immediately at the place of definition.** Since `a` and `3.0` are synonymous in the first lines of the program, the function `f` is really defined as `let f z = 3.0 * z`. Advice

Functions do not need a name, but may be declared as an *anonymous function* using the `fun` keyword and the “`->`” lexeme, as shown in Listing 6.25. · anonymous function
· `fun`
· `->`

Listing 6.25 `functionDeclarationAnonymous.fsx`:
Anonymous functions are functions as values.

```
1 let first = fun x y -> x
2 do printfn "%d" (first 5 3)

-----

1 $ fsharp --nologo functionDeclarationAnonymous.fsx
2 $ mono functionDeclarationAnonymous.exe
3 5
```

Here, a name is bound to an anonymous function which returns the first of two arguments. The difference to `let first x y = x` is that anonymous functions may be treated as values, meaning that they may be used as arguments to other functions and the new values may be reassigned to their identifiers when mutable, as will be discussed in Section 6.7. A common use of anonymous functions is as arguments to other functions, as demonstrated in Listing 6.26.

Listing 6.26 `functionDeclarationAnonymousAdvanced.fsx`:
Anonymous functions are often used as arguments for other functions.

```
1 let apply f x y = f x y
2 let mul = fun a b -> a * b
3 do printfn "%d" (apply mul 3 6)

-----

1 $ fsharp --nologo functionDeclarationAnonymousAdvanced.fsx
2 $ mono functionDeclarationAnonymousAdvanced.exe
3 18
```

Note that here `apply` is given 3 arguments: the function `mul` and 2 integers. It is not given the result of `mul 3 6`, since that would not match the definition of `apply`. **Anonymous functions and functions as arguments are powerful concepts, but tend to make programs harder to read, and their use should be limited.** Advice

The result of one function is often used as an argument of another. This is function composition, and an example is shown in Listing 6.27.

Listing 6.27 functionComposition.fsx:
Composing functions using intermediate bindings.

```

1  let f x = x + 1
2  let g x = x * x
3
4  let a = f 2
5  let b = g a
6  let c = g (f 2)
7  do printfn "a = %A, b = %A, c = %A" a b c

```

```

1  $ fsharp --nologo functionComposition.fsx
2  $ mono functionComposition.exe
3  a = 3, b = 9, c = 9

```

In the example we combine two functions `f` and `g` by storing the result of `f 2` in `a` and using that as argument of `g`. This is the same as `g (f 2)`, and in the later case, the compile creates a temporary value for `f 2`. Such compositions are so common in F# that a special set of operators has been invented, called the *piping* operators: “`|>`” and “`<|`”. They are used as demonstrated in Listing 6.28.

· piping
· `|>`
· `<|`

Listing 6.28 functionPiping.fsx:
Composing functions by piping.

```

1  let f x = x + 1
2  let g x = x * x
3
4  let a = g (f 2)
5  let b = 2 |> f |> g
6  let c = g <| (f <| 2)
7  do printfn "a = %A, b = %A, c = %A" a b c

```

```

1  $ fsharp --nologo functionPiping.fsx && mono
    functionPiping.exe
2  a = 9, b = 9, c = 9

```

The example shows regular composition, left-to-right, and right-to-left piping. The word piping is a pictorial description of data as if it were flowing through pipes, where functions are connection points of pipes distributing data in a network. The three expressions in Listing 6.28 perform the same calculation. The left-to-right piping in line 5 corresponds to the left-to-right reading direction, i.e., the value 2 is used as argument to `f`, and the result is used as argument to `g`. In contrast, right-to-left piping in line 6 has the order of arithmetic composition as line 4. Unfortunately, since the piping operators are left-associative, without the parenthesis in line 6 `g <| f <| 2`, F# would read the expression as `(g <| f) <| 2`. That would have been an error, since `g` takes an integer as argument, not a function. F# can also define composition on a function level. Further discussion on this is deferred to Chapter 16. The piping operator comes in four variants: “`||>`”, “`<||`”, “`||||>`”, and “`<|||`”. These allow for piping between pairs and triples to functions of 2 and 3 arguments, see Listing 6.29 for an example.

Listing 6.29 functionTuplePiping.fsx:

Tuples can be piped to functions of more than one argument.

```

1  let f x = printfn "%A" x
2  let g x y = printfn "%A %A" x y
3  let h x y z = printfn "%A %A %A" x y z
4
5  1 |> f
6  (1, 2) ||> g
7  (1, 2, 3) |||> h

```

```

1  $ fsharp --nologo functionTuplePiping.fsx
2  $ mono functionTuplePiping.exe
3  1
4  1 2
5  1 2 3

```

The example demonstrates right-to-left piping, left-to-right works analogously.³

A *procedure* is a generalization of the concept of functions, and in contrast to functions, procedures need not return values. This is demonstrated in Listing 6.30.

Listing 6.30 procedure.fsx:

A procedure is a function that has no return value, and in F# returns “()”.

```

1  let printIt a = printfn "This is '%A'" a
2  do printIt 3
3  do printIt 3.0

```

```

1  $ fsharp --nologo procedure.fsx && mono procedure.exe
2  This is '3'
3  This is '3.0'

```

In F#, this is automatically given the unit type as the return value. Procedural thinking is useful for *encapsulation* of scripts, but is prone to *side-effects*. For this reason, it is advised to **prefer functions over procedures**. More on side-effects in Section 6.7.

In F#, functions (and procedures) are *first-class citizens*, which means that functions are values: They may be passed as arguments, returned from a function, and bound to a name. For first-class citizens, the name it is bound to does not carry significance to the language, as, e.g., illustrated with the use of anonymous functions. Technically, a function is stored as a *closure*. A closure is a description of the function, its arguments, its expression, and the environment at the time it was created, i.e., the triple $(args, exp, env)$. Consider the listing in Listing 6.31.

- encapsulation
- side-effects
- Advice
- first-class citizens
- closure

³Jon: Tuples have not yet been introduced!

Listing 6.31 functionFirstClass.fsx:The function `ApplyFactor` has a non-trivial closure.

```

1  let mul x y = x * y
2  let factor = 2.0
3  let applyFactor fct x =
4      let a = fct factor x
5      string a
6
7  do printfn "%g" (mul 5.0 3.0)
8  do printfn "%s" (applyFactor mul 3.0)

```

```

1  $ fsharpc --nologo functionFirstClass.fsx && mono
   functionFirstClass.exe
2  15
3  6

```

It defines two functions `mul` and `applyFactor`, where the latter is a higher order function taking another function as an argument and uses part of the environment to produce its result. The two closures are:

$$\text{mul} : (\text{args}, \text{exp}, \text{env}) = ((x, y), (x * y), ()) \quad (6.3)$$

$$\text{applyFactor} : (\text{args}, \text{exp}, \text{env}) = ((x, \text{fct}), (\text{let } a = \text{fct factor } x, (\text{factor} \rightarrow 2.0))) \quad (6.4)$$

The function `mul` does not use its environment, and everything needed to evaluate its expression are values for its arguments. The function `applyFactor` also takes two arguments, a function and a value. It uses `factor` from the environment, thus this is stored in its closure. When `mul` is given as an argument in Listing 6.31 line 8, then it is its closure which is given to `applyFactor`, and the closure contains everything that `applyFactor` requires to use `mul`. Likewise, if `applyFactor` is given as argument to yet another function, then its closure includes the relevant part of its environment at the time of definition, `factor`, such that when `applyFactor` is applied to two arguments, then its closure contains everything needed to evaluate its expression.

6.3. Operators

Operators are functions, and in F#, the infix multiplication operator `+` is equivalent to the function `(+)`, as shown in Listing 6.32.

Listing 6.32 addOperatorNFunction.fsx:

Operators have function equivalents.

```

1 let a = 3.0
2 let b = 4.0
3 let c = a + b
4 let d = (+) a b
5 do printfn "%A plus %A is %A and %A" a b c d

```

```

1 $ fsharp --nologo addOperatorNFunction.fsx
2 $ mono addOperatorNFunction.exe
3 3.0 plus 4.0 is 7.0 and 7.0

```

All operators have this option, and you may redefine them and define your own operators, but in F# names of user-defined operators are limited:

- A *unary operator* name can be: “+”, “-”, “+.”, “-.”, “%”, “&”, “&&”, “~”, “~~”, “~~~”, “~~~~”, ..., apostropheOp. Here apostropheOp is an operator name starting with “!” and followed by one or more of either “!”, “%”, “&”, “*”, “+”, “-”, “.”, “/”, “<”, “=”, “>”, “@”, “^”, “|”, “~”, but apostropheOp cannot be “!=”.
- A *binary operator* name can be: “+”, “-”, “+.”, “-.”, “%”, “&”, “&&”, “:=”, “:.”, “\$”, “?”, dotOp. Here dotOp is an operator name starting with “.” and followed by “+”, “-”, “+.”, “-.”, “%”, “&”, “&&”, “-”, “+”, “|”, “<”, “>”, “=”, “|”, “&”, “^”, “*”, “/”, “%”, “!=”. Only “?” and “?<-” may start with “?”.

The precedence rules and associativity of user-defined operators follow the rules for which they share prefixes with built-in rules, see Table E.5. E.g., `.*`, `+++`, and `<+` are valid operator names for infix operators, they have precedence as ordered, and their associativities are all left. Using `~` as the first character in the definition of an operator makes the operator unary and will not be part of the name. Examples of definitions and use of operators are,

Listing 6.33 operatorDefinitions.fsx:

Operators may be (re)defined by their function equivalent.

```

1 let (.*) x y = x * y + 1
2 printfn "%A" (3 .* 4)
3 let (+++) x y = x * y + y
4 printfn "%A" (3 +++ 4)
5 let (<+) x y = x < y + 2.0
6 printfn "%A" (3.0 <+ 4.0)
7 let (~+.) x = x+1
8 printfn "%A" (+.1)

```

```

1 $ fsharp --nologo operatorDefinitions.fsx
2 $ mono operatorDefinitions.exe
3 13
4 16
5 true
6 2

```

Operators beginning with `*` must use a space in its definition. For example, without a

space (`*` would be confused with the beginning of a comment (`*`, see Chapter 7 for more on comments in the code.

Beware, redefining existing operators lexically redefines all future uses of the operators for all types, hence **it is not a good idea to redefine operators, but better to define new ones**. In Chapter 20 we will discuss how to define type-specific operators, including prefix operators. Advice

6.4. Do Bindings

Aside from `let` bindings that binds names with values or functions, sometimes we just need to execute code. This is called a `do` binding or, alternatively, a *statement*. The syntax is as follows:

· `do`
· `do` binding
· *statement*

Listing 6.34: Syntax for `do` bindings.

```
1 [do ]<expr>
```

The expression `<expr>` must return `unit`. The keyword `do` is optional in most cases, but using it emphasizes that the expression is not a function that returns a useful value. Procedures are examples of such expressions, and a very useful family of procedures are the `printf` family described below. In the remainder of this book, we will refrain from using the `do` keyword.

6.5. The Printf Function

A common way to output information to the console is to use one of the family of *printf* commands. These functions are special, since they take a variable number of arguments, and the number is decided by the first argument - the format string. The syntax for the `printf` commands are as follows: · `printf`

Listing 6.35: `printf` statement.

```
1 printf <format-string> {<ident>}
```

The `formatString` is a string (simple or verbatim) with placeholders. The function `printf` prints `formatString` to the console, where all placeholder have been replaced by the values of the corresponding arguments formatted as specified. For example, in `printfn "1 2 %d" 3`, the `formatString` is `"1 2 %d"` and the placeholder is `%d`. When executed, `printf` will replace `%d` with the following argument, `3`, and print the result to the console: `1 2 3`. There are specifiers for all the basic types, and more, as elaborated in Table 6.2. The placeholder can be parametrized, e.g., the placeholder string `%8s` will print a right-aligned string which that is eight characters wide and padded with spaces, as needed. For floating point numbers, `%8f` will print a number that is exactly seven digits and a decimal point, making eight characters in total. Zeros are added after the decimal point, as needed. Alternatively, we may specify the number of digits after the decimal point, such that `%8.1f` will print a floating point number, aligned to the right, with one

6. Values and Functions

Specifier	Type	Description
<code>%b</code>	<code>bool</code>	replaces with boolean value
<code>%s</code>	<code>string</code>	
<code>%c</code>	<code>char</code>	
<code>%d, %i</code>	basic integer	
<code>%u</code>	basic unsigned integers	
<code>%x</code>	basic integer	formatted as unsigned hexadecimal with lower case letters
<code>%X</code>	basic integer	formatted as unsigned hexadecimal with upper case letters
<code>%o</code>	basic integer	formatted as unsigned octal integer
<code>%f, %F,</code>	basic floats	formatted on decimal form
<code>%e, %E,</code>	basic floats	formatted on scientific form. Lower case uses "e" while upper case uses "E" in the formatting.
<code>%g, %G,</code>	basic floats	formatted on the shortest of the corresponding decimal or scientific form.
<code>%M</code>	decimal	
<code>%O</code>	Objects <code>ToString</code> method	
<code>%A</code>	any built-in types	formatted as a literal type
<code>%a</code>	<code>Printf.TextWriterFormat -> 'a -> ()</code>	
<code>%t</code>	<code>(Printf.TextWriterFormat -> ()</code>	

Table 6.2.: Printf placeholder string

digit after the decimal point padded with spaces, as needed. The default is for the value to be right justified in the field, but left justification can be specified by the `-` character. For number types, you can specify their format by `"0"` for padding the number with zeros to the left when right justifying the number; `"+"` to explicitly show a plus sign for positive numbers; `SP` to enforce a space, where there otherwise would be a plus sign for positive numbers. The placeholder parameter may also be given as an argument to `printf` which case the placeholder should use the `*` character instead of an integer.

Examples of placeholder parametrization are shown in Listing 6.36.

Listing 6.36 printfExample.fsx:

Examples of printf and some of its formatting options.

```

1 let pi = 3.1415192
2 let hello = "hello"
3 printf "An integer: %d\n" (int pi)
4 printf "A float %f on decimal form and on %e scientific
   form\n" pi pi
5 printf "A char '%c' and a string \"%s\"\n" hello.[0] hello
6 printf "Float using width 8 and 1 number after the decimal:\n"
7 printf "  \"%8.1f\" \" \"%8.1f\" \"\n" pi -pi
8 printf "  \"%08.1f\" \" \"%08.1f\" \"\n" pi -pi
9 printf "  \"% 8.1f\" \" \"% 8.1f\" \"\n" pi -pi
10 printf "  \"%-8.1f\" \" \"%-8.1f\" \"\n" pi -pi
11 printf "  \"%+8.1f\" \" \"%+8.1f\" \"\n" pi -pi
12 printf "  \"%8s\" \"\n\" \"%-8s\" \"\n" "hello" "hello"

```

```

1 $ fsharp --nologo printfExample.fsx && mono printfExample.exe
2 An integer: 3
3 A float 3.141519 on decimal form and on 3.141519e+000
   scientific form
4 A char 'h' and a string "hello"
5 Float using width 8 and 1 number after the decimal:
6   "      3.1" "      -3.1"
7   "000003.1" "-00003.1"
8   "      3.1" "      -3.1"
9   "3.1      " "-3.1      "
10  "      +3.1" "      -3.1"
11  "    hello"
12 "hello      "

```

Not all combinations of flags and identifier types are supported, e.g., strings cannot have the number of integers after the decimal point specified. The placeholder types "%A", "%a", and "%t" are special for F#, examples of their use are shown in Listing 6.37.

Listing 6.37 printfExampleAdvance.fsx:

Custom format functions may be used to specialise output.

```

1 let noArgument writer = printf "I will not print anything"
2 let customFormatter writer arg = printf "Custom formatter got:
   \"%A\" \" \" arg
3 printf "Print examples: %A, %A, %A\n" 3.0m 3uy "a string"
4 printf "Print function with no arguments: %t\n" noArgument
5 printf "Print function with 1 argument: %a\n" customFormatter

1 $ fsharp --nologo printfExampleAdvance.fsx
2 $ mono printfExampleAdvance.exe
3 Print examples: 3.0M, 3uy, "a string"
4 Print function with no arguments: I will not print anything
5 Print function with 1 argument: Custom formatter got: "3.0"

```

The %A is special in that all built-in types, including tuples, lists, and arrays to be discussed

Function	Example	Description
<code>printf</code>	<code>printf "%d apples" 3</code>	Prints to the console, i.e., <code>stdout</code>
<code>printfn</code>		As <code>printf</code> and adds a newline.
<code>fprintf</code>	<code>fprintf stream "%d apples" 3</code>	Prints to a stream, e.g., <code>stderr</code> and <code>stdout</code> , which would be the same as <code>printf</code> and <code>eprintf</code> .
<code>fprintfn</code>		As <code>fprintf</code> but with added newline.
<code>eprintf</code>	<code>eprintf "%d apples" 3</code>	Prints to <code>stderr</code>
<code>eprintfn</code>		As <code>eprintf</code> but with added newline.
<code>sprintf</code>	<code>printf "%d apples" 3</code>	Return printed string
<code>failwithf</code>	<code>failwithf "%d failed apples" 3</code>	Prints to a string and used for raising an exception.

in Chapter 11, can be printed using this formatting string, but notice that the formatting performed includes the named literal string. The two formatting strings `%t` and `%a` are options for user-customizing the formatting and will not be discussed further.

Beware, `formatString` is not a `string` but a `Printf.TextWriterFormat`, so to predefine a `formatString` as, e.g., `let str = "hello %s" in printf str "world"`, will be a type error.

The family of `printf` is shown in Table 6.3. The function `fprintf` prints to a stream, e.g., `stderr` and `stdout`, of type `System.IO.TextWriter`. For the moment it is sufficient to think of both `stderr` and `stdout` to be the console. Streams will be discussed in further detail in Chapter 19. The function `failwithf` is used with exceptions, see Chapter 18 for more details. The function has a number of possible return value types, and for testing, the `ignore` function ignores it all, e.g., `ignore (failwithf "%d failed apples" 3)`. · ignore

6.6. Reading from the Console

The `printf` and `printfn` functions allow us to write text on the screen. A program often needs to ask a user to input data, e.g., by typing text on a keyboard. Text typed on the keyboard is accessible through the `stdin` stream, and F# provides several library functions for capturing text typed on the keyboard. In the following section, we will briefly discuss the `System.Console.ReadLine` function. For more details and other methods of input see Chapters 19 and 23.

The function `System.Console.ReadLine` takes a unit value as an argument and returns the string the user typed. The program will not advance until the user presses newline. An example of a program that multiplies two floating point numbers supplied by a user is given in Listing 6.38,

Listing 6.38 `userDialoguePrintf.fsx`:
Interacting with a user using `ReadLine`.

```
1 printfn "To perform the multiplication of a and b"
2 printf "Enter a: "
3 let a = float (System.Console.ReadLine ())
4 printf "Enter b: "
5 let b = float (System.Console.ReadLine ())
6 printfn "a * b = %A" (a * b)
```

and an example dialogue is shown in Listing 6.39.

Listing 6.39: An example dialogue of running Listing 6.38. What the user typed has been framed in red boxes.

```
1 $ fsharp --nologo userDialoguePrintf.fsx && mono
   userDialoguePrintf.exe
2 To perform the multiplication of a and b
3 Enter a: 3.5
4 Enter b: 7.4
5 a * b = 25.9
```

Note that the string is immediately cast to floats such that we can multiply the input using the float multiplication operator. This also implies that if the user inputs a non-number, then `mono` will halt with an error message.

6.7. Variables

Identifiers may be mutable, which means that the it may be rebound to a new value. Mutable identifiers are specified using the *mutable* keyword with the following syntax:

· *mutable*

Listing 6.40: Syntax for defining mutable values with an initial value.

```
1 let mutable <ident> = <expr> [in <expr>]
```

Changing the value of an identifier is called *assignment* and is done using the “<-” lexeme. Assignments have the following syntax:⁴

· assignment
· <-

Listing 6.41: Value reassignment for mutable variables.

```
1 <ident> <- <ident>
```

Mutable data is synonymous with the term *variable*. A variable is an area in the computer’s working memory associated with an identifier and a type, and this area may be read from and written to during program execution, see Listing 6.42 for an example.

· mutable data
· variable

⁴Jon: Discussion on heap and stack should be added here.

Listing 6.42 mutableAssignReassingShort.fsx:

A variable is defined and later reassigned a new value.

```

1  let mutable x = 5
2  printfn "%d" x
3  x <- -3
4  printfn "%d" x

```

```

1  $ fsharp --nologo mutableAssignReassingShort.fsx
2  $ mono mutableAssignReassingShort.exe
3  5
4  -3

```

Here, an area in memory was denoted `x`, initially assigned the integer value 5, hence the type was inferred to be `int`. Later, this value of `x` was replaced with another integer using the “<-” lexeme. The “<-” lexeme is used to distinguish the assignment from the comparison operator. For example, the statement `a = 3` in Listing 6.43 is not an assignment but a comparison which is evaluated to be false.

Listing 6.43: It is a common error to mistake “=” and “<-” lexemes for mutable variables.

```

1  > let mutable a = 0
2  - a = 3;;
3  val mutable a : int = 0
4  val it : bool = false

```

However, it is important to note that when the variable is initially defined, then the “=” operator must be used, while later reassignments must use the “<-” expression.

Assignment type mismatches will result in an error, as demonstrated in Listing 6.44.

Listing 6.44 mutableAssignReassingTypeError.fsx:

Assignment type mismatching causes a compile-time error.

```

1  let mutable x = 5
2  printfn "%d" x
3  x <- -3.0
4  printfn "%d" x

```

```

1  $ fsharp --nologo mutableAssignReassingTypeError.fsx
2
3  mutableAssignReassingTypeError.fsx(3,6): error FS0001: This
    expression was expected to have type
4      'int'
5  but here has type
6      'float'
7  $ mono mutableAssignReassingTypeError.exe
8  Cannot open assembly 'mutableAssignReassingTypeError.exe': No
    such file or directory.

```

I.e., once the type of an identifier has been declared or inferred, it cannot be changed.

A typical variable is a counter of type integer, and a typical use of counters is to increment them, see Listing 6.45 for an example.

Listing 6.45 mutableAssignIncrement.fsx:
Variable increment is a common use of variables.

```

1  let mutable x = 5 // Declare a variable x and assign the value
    5 to it
2  printfn "%d" x
3  x <- x + 1 // Increment the value of x
4  printfn "%d" x

```

```

1  $ fsharpc --nologo mutableAssignIncrement.fsx
2  $ mono mutableAssignIncrement.exe
3  5
4  6

```

Using variables in expressions, as opposed to the left-hand-side of an assignment operation, reads the value of the variable. Thus, when using a variable as the return value of a function, then the value is copied from the local scope of the function to the scope from which it is called. This is demonstrated in Listing 6.46.

Listing 6.46: Returning a mutable variable returns its value.

```

1  > let g () =
2  -   let mutable y = 0
3  -   y
4  -   printfn "%d" (g ());;
5  0
6  val g : unit -> int
7  val it : unit = ()

```

In the example we see that the type is a value, and not mutable.

Variables implement dynamic scope, that is, the value of an identifier depends on *when* it is used. This is in contrast to lexical scope, where the value of an identifier depends on *where* it is defined. As an example, consider the script in Listing 6.24 which defines a function using lexical scope and returns the number 6.0, however, if `a` is made `mutable`, then the behavior is different, as shown in Listing 6.47.

Listing 6.47 dynamicScopeNFunction.fsx:

Mutual variables implement dynamic scope rules. Compare with Listing 6.24.

```

1 let testScope x =
2     let mutable a = 3.0
3     let f z = a * z
4     a <- 4.0
5     f x
6 printfn "%A" (testScope 2.0)

1 $ fsharp --nologo dynamicScopeNFunction.fsx
2 $ mono dynamicScopeNFunction.exe
3 8.0

```

Here, the response is 8.0, since the value of `a` changed before the function `f` was called.

6.8. Reference Cells

F# has a variation of mutable variables called *reference cells*. Reference cells have the built-in function `ref` and the operators “!” and “:=”, where `ref` creates a reference variable, and the “!” and the “:=” operators respectively reads and writes its value. An example of using reference cells is given in Listing 6.48.

· reference cells
· `ref`
· “:=”

Listing 6.48 refCell.fsx:

Reference cells are variants of mutable variables.

```

1 let x = ref 0
2 printfn "%d" !x
3 x := !x + 1
4 printfn "%d" !x

1 $ fsharp --nologo refCell.fsx && mono refCell.exe
2 0
3 1

```

Reference cells are different from mutable variables, since their content is allocated on *The Heap*. The Heap is a global data storage that is not destroyed when a function returns, which is in contrast to the *call stack*, also known as *The Stack*. The Stack maintains all the local data for a specific instance of a function call, see Section 13.2 for more details. As a consequence, when a reference cell is returned from a function, then it is the reference to the location on The Heap, which is returned as a value. Since this points outside the local data area of the function, this location is still valid after the function returns, and the variable stored there is accessible to the caller. This is illustrated in Figure 6.1

· The Heap
· call stack
· The Stack

Reference cells may cause *side-effects*, where variable changes are performed across independent scopes. Some side-effects are useful, e.g., the `printf` family changes the content of the screen, and the screen is outside the scope of the caller. Another example of a useful side-effect is a counter shown in Listing 6.49.

· side-effects

Figure 6.1.: A reference cell is a pointer to The Heap, and the content is not destroyed when its reference falls out of scope.

Listing 6.49 refEncapsulation.fsx:

An increment function with a local state using a reference cell.

```

1  let incr =
2      let counter = ref 0
3      fun () ->
4          counter := !counter + 1
5          !counter
6  printfn "%d" (incr ())
7  printfn "%d" (incr ())
8  printfn "%d" (incr ())

1  $ fsharp --nologo refEncapsulation.fsx && mono
   refEncapsulation.exe
2  1
3  2
4  3

```

Here `incr` is an anonymous function with an internal state `counter`. At first glance, it may be surprising that `incr ()` does not return the value 1 at every call. The reason is that the value of the `incr` is the closure of the anonymous function `fun () -> counter := ...`, which is

$$\text{incr} : (\text{args}, \text{exp}, \text{env}) = ((\text{counter} := !\text{counter} + 1), (\text{counter} \rightarrow \text{ref } 0)). \quad (6.5)$$

Thus, `counter` is only initiated once at the initial binding, while every call of `incr ()` updates its value on The Heap. Such a programming structure is called *encapsulation*, since the `counter` state has been encapsulated in the anonymous function, and the only way to access it is by calling the same anonymous function. In general, it is advisable to use encapsulation to hide implementation details irrelevant to the user of the code. Advice

The `incr` example in Listing 6.49 is an example of a useful side-effect. An example to be avoided is shown in Listing 6.50.

Listing 6.50 refSideEffect.fsx:

Intertwining independent scopes is typically a bad idea.

```

1  let updateFactor factor =
2      factor := 2
3
4  let multiplyWithFactor x =
5      let a = ref 1
6      updateFactor a
7      !a * x
8
9  printfn "%d" (multiplyWithFactor 3)

```

```

1  $ fsharpc --nologo refSideEffect.fsx && mono refSideEffect.exe
2  6

```

In the example, the function `updateFactor` changes a variable in the scope of the function `multiplyWithFactor`. The code style is prone to errors, since the computations are not local at the place of writing, i.e., in `multiplyWithFactor`, and if `updateFactor` were defined in a library, then the source code may not be available. Better style of programming is shown in Listing 6.51.

Listing 6.51 refWithoutSideEffect.fsx:

A solution similar to Listing 6.50 without side-effects.

```

1  let updateFactor () =
2      2
3
4  let multiplyWithFactor x =
5      let a = ref 1
6      a := updateFactor ()
7      !a * x
8
9  printfn "%d" (multiplyWithFactor 3)

```

```

1  $ fsharpc --nologo refWithoutSideEffect.fsx
2  $ mono refWithoutSideEffect.exe
3  6

```

Here, there can be no doubt in `multiplyWithFactor` that the value of `a` is changing. Side-effects do have their use, but should, in general, be avoided at almost all costs, and it is advised to **minimize the use of side effects**.

Advice

Reference cells give rise to an effect called *aliasing*, where two or more identifiers refer to the same data, as illustrated in Listing 6.52. · aliasing

Listing 6.52 refCellAliasing.fsx:

Aliasing can cause surprising results and should be avoided.

```

1  let a = ref 1
2  let b = a
3  printfn "%d, %d" !a !b
4  b := 2
5  printfn "%d, %d" !a !b

```

```

1  $ fsharp --nologo refCellAliasing.fsx && mono
    refCellAliasing.exe
2  1, 1
3  2, 2

```

Here, `a` is defined as a reference cell, and by defining `b` to be equal to `a`, we have created an alias. This can be very confusing since as the example shows, changing the value of `b` causes `a` to change as well. Aliasing is a variant of side-effects, and **aliasing should be avoided at all costs**. Advice

Since F# version 4.0, the compiler has automatically converted mutable variables to reference cells, where needed. E.g., Listing 6.49 can be rewritten using a mutable variable, as shown in Listing 6.53.

Listing 6.53 mutableEncapsulation.fsx:

Local mutable content can be indirectly accessed outside its scope.

```

1  let incr =
2      let mutable counter = 0
3      fun () ->
4          counter <- counter + 1
5          counter
6  printfn "%d" (incr ())
7  printfn "%d" (incr ())
8  printfn "%d" (incr ())

```

```

1  $ fsharp --nologo mutableEncapsulation.fsx
2  $ mono mutableEncapsulation.exe
3  1
4  2
5  3

```

Reference cells are preferred over mutable variables for encapsulation, in order to avoid confusion.

6.9. Tuples

Tuples are a direct extension of constants. They are immutable and have neither concatenations nor indexing operations. Tuples are unions of immutable types and have the following syntax:

Listing 6.54: Tuples are list of expressions separated by commas.

```
1 <expr>{, <expr>}
```

Tuples are identified by the “,” lexeme and often enclosed in parentheses, but that is not required. An example is a triple, also known as a 3-tuple, (2,true,"hello"). In interactive mode, the type of tuples is demonstrated in Listing 6.55.

Listing 6.55: Tuple types are products of sets.

```
1 > let tp = (2, true, "hello")
2 - printfn "%A" tp;;
3 (2, true, "hello")
4 val tp : int * bool * string = (2, true, "hello")
5 val it : unit = ()
```

The values 2, true, and "hello" are *members*, and the number of elements of a tuple is its *length*. From the response of F#, we see that the tuple is inferred to have the type `int * bool * string`. The “*” denotes the Cartesian product between sets. Tuples can be products of any types and follow the lexical scope rules like value and function bindings. Notice also that a tuple may be printed as a single entity by the %A placeholder. In the example we bound `tp` to the tuple. The opposite is also possible, as demonstrated in Listing 6.56.

Listing 6.56: Definition of a tuple.

```
1 > let deconstructNPrint tp =
2 - let (a, b, c) = tp
3 - printfn "tp = (%A, %A, %A)" a b c
4 -
5 - deconstructNPrint (2, true, "hello")
6 - deconstructNPrint (3.14, "Pi", 'p');;
7 tp = (2, true, "hello")
8 tp = (3.14, "Pi", 'p')
9 val deconstructNPrint : 'a * 'b * 'c -> unit
10 val it : unit = ()
```

In this example, a function is defined that takes 1 argument, a 3-tuple. If we wanted a function with 3 arguments, then the function binding should have been `let deconstructNPrint a b c = ...`. The value binding `let (a, b, c) = tp`, binds a tuple with 3 named members to a value, thus deconstructing it in terms of its members. This is called pattern matching and will be discussed in further details in Chapter 15. Since we used the %A placeholder in the `printfn` function, the function can be called with 3-tuples of different types. F# informs us that the tuple type is variable by writing `'a * 'b * 'c`. The “'” notation means that the type can be decided at run-time, see Section 14.6 for more on variable types.

Pairs or 2-tuples are so common that F# includes two built-in functions, `fst` and `snd`, to extract the first and second element of a pair. This is demonstrated in Listing 6.57.

Listing 6.57 pair.fsx:Deconstruction of pairs with the built-in functions `fst` and `snd`.

```

1 let pair = ("first", "second")
2 printfn "fst(pair) = %s, snd(pair) = %s" (fst pair) (snd pair)

```

```

1 $ fsharp --nologo pair.fsx && mono pair.exe
2 fst(pair) = first, snd(pair) = second

```

Tuples of equal lengths can be compared, and the comparison is defined similarly to string comparison. Tuples of equal length are compared element by element. E.g., $(1,2) = (1,3)$ is false, while $(1,2) = (1,2)$ is true. The “<” operator is the boolean negation of the “=” operator. For the “<”, “<=”, “>”, and “>=” operators, the strings are ordered lexicographically, such that $(\text{'a'}, \text{'b'}, \text{'c'}) < (\text{'a'}, \text{'b'}, \text{'s'})$ && $(\text{'a'}, \text{'b'}, \text{'s'}) < (\text{'c'}, \text{'o'}, \text{'s'})$ is true, that is, the “<” operator on two tuples is true if and only if the left operand should come before the right when sorting alphabetically. See Listing 6.58 for an example.

Listing 6.58 tupleCompare.fsx:

Tuples comparison is similar to string comparison.

```

1 let lessThan (a, b, c) (d, e, f) =
2     if a <> d then a < d
3     elif b <> e then b < d
4     elif c <> f then c < f
5     else false
6
7 let printTest x y =
8     printfn "%A < %A is %b" x y (lessThan x y)
9
10 let a = ('a', 'b', 'c');
11 let b = ('d', 'e', 'f');
12 let c = ('a', 'b', 'b');
13 let d = ('a', 'b', 'd');
14 printTest a b
15 printTest a c
16 printTest a d

```

```

1 $ fsharp --nologo tupleCompare.fsx && mono tupleCompare.exe
2 ('a', 'b', 'c') < ('d', 'e', 'f') is true
3 ('a', 'b', 'c') < ('a', 'b', 'b') is false
4 ('a', 'b', 'c') < ('a', 'b', 'd') is true

```

The algorithm for deciding the boolean value of $(a_1, a_2) < (b_1, b_2)$ is as follows: we start by examining the first elements, and if a_1 and b_1 are different, then the result of $(a_1, a_2) < (b_1, b_2)$ is equal to the result of $a_1 < b_1$. If a_1 and b_1 are equal, then we move on to the next letter and repeat the investigation. The “<=”, “>”, and “>=” operators are defined similarly.

Binding tuples to mutables does not make the tuple mutable. This is demonstrated in Listing 6.59.

Listing 6.59 tupleOfMutables.fsx:

A mutable changes value, but the tuple defined by it does not refer to the new value.

```

1  let mutable a = 1
2  let mutable b = 2
3  let c = (a, b)
4  printfn "%A, %A, %A" a b c
5  a <- 3
6  printfn "%A, %A, %A" a b c

$ fsharp -nologo tupleOfMutables.fsx && mono
tupleOfMutables.exe
1, 2, (1, 2)
3, 2, (1, 2)

```

However, it is possible to define a mutable variable of type tuple such that new tuple values can be assigned to it, as shown in Listing 6.60.

Listing 6.60 mutableTuple.fsx:

A mutable tuple can be assigned a new value.

```

1  let mutable pair = 1,2
2  printfn "%A" pair
3  pair <- (3,4)
4  printfn "%A" pair

$ fsharp -nologo mutableTuple.fsx && mono mutableTuple.exe
(1, 2)
(3, 4)

```

Mutable tuples are value types, meaning that binding to new names makes copies, not aliases, as demonstrated in Listing 6.61.

Listing 6.61 mutableTupleValue.fsx:

A mutable tuple is a value type.

```

1  let mutable pair = 1,2
2  let mutable aCopy = pair
3  pair <- (3,4)
4  printfn "%A %A" pair aCopy

$ fsharp -nologo mutableTupleValue.fsx && mono
mutableTupleValue.exe
(3, 4) (1, 2)

```

The use of tuples shortens code and highlights semantic content at a higher level, e.g., instead of focusing on the elements, tuples focus on their union. While this may look elegant and short there is the risk of *obfuscation*, i.e., writing compact code that is difficult to read, where an unprepared reader of the code may not easily understand the computation

6. *Values and Functions*

nor appreciate its elegance without an accompanying explanation. Hence, **always keep an eye out for compact and concise ways to write code, but never at the expense of readability.** Advice

7 | In-code Documentation

Documentation is a very important part of writing programs, since it is most unlikely that you will be writing really obvious code. Moreover, what seems obvious at the point of writing may be mystifying months later to the author and to others. Documentation serves several purposes:

1. Communicate what the code should be doing.
2. Highlight big insights essential for the code.
3. Highlight possible conflicts and/or areas where the code could be changed later.

The essential point is that coding is a journey in problem-solving, and proper documentation is an aid in understanding the solution and the journey that lead to it. Documentation is most often a mixture of in-code documentation and accompanying documents. Here, we will focus on in-code documentation which arguably causes problems in multi-language environments and run the risk of bloating code.

F# has two different syntaxes for comments. Comments can be block comments: ¹

Listing 7.1: Block comments.

```
1  (*<any text>*)
```

The comment text (<any text>) can be any text and is still parsed by F# as keywords and basic types, implying that `(* a comment (* in a comment *) *)` and `(* " ") *` are valid comments, while `(* " *)` is invalid.

Alternatively, comments may also be line comments,

Listing 7.2: Line comments.

```
1  //<any text>
```

where the comment text ends after the first newline.

The F# compiler has an option for generating *Extensible Markup Language (XML)* files from scripts using the C# documentation comments tags². The XML documentation starts

- Extensible Markup Language
- XML

with a triple-slash `///`, i.e., a `lineComment` and a slash, which serve as comments for the code construct that follows immediately after. XML consists of tags which always appear in pairs, e.g., the tag “tag” would look like `<tag> ... </tag>`. F# accept any tags, but recommends those listed in Table 7.1. If no tags are used, then it is automatically assumed to be a `<summary>`. An example of a documented script is shown in Listing 7.3. is:

The extracted XML is written in C# type by convention, since F# is part of the Mono and .Net framework that may be used by any of the languages using Assemblies. Besides the XML inserted in the script, the XML has added the `<?xml ...>` header, `<doc>`, `<assembly>`, `<members>`, and `<member>` tags. The header and the `<doc>` tag are standards for XML. The extracted XML is geared towards documenting big libraries of codes and thus highlights the structured programming organisation, see Chapters 9 and 20, and `<assembly>`, `<members>`, and `<member>` are indications for where the functions belong in the hierarchy. As an example, the prefix `M:CommentExample.` indicates that the method is in the namespace `commentExample`, which in this case is the name of the file. Furthermore, the function type `val solution : a:float -> b:float -> c:float -> sgn:float -> float` is in the XML documentation

```
M:CommentExample.solution(System.Double,System.Double,System.Double,System.Double),
```

which is the C# equivalent.

An accompanying program in the Mono suite is `mdoc`, whose primary use is to perform a

syntax analysis of an assembly and generate a scaffold XML structure for an accompanying document. With the `-i` flag, it is further possible to include the in-code comments as initial descriptions in the XML. The XML may be updated gracefully by `mdoc` as the code develops, without destroying manually entered documentation in the accompanying documentation. Finally, the XML may be exported to HTML.

The primary use of the `mdoc` command is to analyze compiled code and generate an empty XML structure with placeholders to describe functions, values, and variables. This structure can be updated and edited as the program develops, and the edited XML files can be exported to *Hyper Text Markup Language* (HTML) files and viewed in any browser. Using the console, all of this is accomplished by the procedure shown in Listing 7.6, and the result is shown in Figure 7.1.

solution Method

Find x when $0 = ax^2 + bx + c$.

Syntax

```
[Microsoft.FSharp.Core.CompilationArgumentCounts(Mono.Cecil.CustomAttributeArgument[])]
public static double solution (double a, double b, double c, double sgn)
```

Parameters

a
Quadratic coefficient.

b
Linear coefficient.

c
Constant coefficient.

sgn
+1 or -1 determines the solution.

Returns

The solution to x .

Remarks

Negative discriminant are not checked.

Example

The following code:

```
Example
let a = 1.0
let b = 0.0
let c = -1.0
let xp = (solution a b c +1.0)
printfn "0 = %.1fx^2 + %.1fx + %.1f => x_+ = %.1f" a b c xp
```

prints $0 = 1.0x^2 + 0.0x + -1.0 \Rightarrow x_+ = 0.7$ to the console.

8 | Controlling Program Flow

Non-recursive functions encapsulate code and allow for control of execution flow. That is, if a piece of code needs to be executed many times, then we can encapsulate it in the body of a function and call this function several times. In this chapter, we will look at more general control of flow via loops and conditional execution. Recursion is another mechanism for controlling flow, but this is deferred to Chapter 13.

8.1. While and For Loops

Many programming constructs need to be repeated, and F# contains many structures for repetition. A *while*-loop has the following syntax:

· *while*

Listing 8.1: While loop.

```
1 while <condition> do <expr> [done]
```

The *condition* *<condition>* is an expression that evaluates to true or false. A while-loop repeats the *<expr>* expression as long as the condition is true. Using lightweight syntax, the block following the *do* keyword up to and including the *done* keyword may be replaced by a newline and indentation.

· *condition*

· *do*

· *done*

The program in Listing 8.5 is an example of a while-loop which counts from 1 to 10.

Listing 8.2 countWhile.fsx:
Count to 10 with a counter variable.

```
1 let mutable i = 1 in while i <= 10 do printf "%d " i; i <- i +  
  1 done;  
2 printf "\n"
```

```
1 $ fsharp --nologo countWhile.fsx && mono countWhile.exe  
2 1 2 3 4 5 6 7 8 9 10
```

The variable *i* is customarily called the counter variable. The counting is done by performing the following computation: In line 1, the counter variable is first given an initial value of 1. Then execution enters the while-loop and examines the condition. Since $1 \leq 10$, the condition is true, and execution enters the body of the loop. The body prints the value of the counter to the screen and increases the counter by 1. Then execution returns to the

8. Controlling Program Flow

top of the while-loop. Now the condition is $2 \leq 10$, which is also true, and so execution enters the body and so on until the counter has reached the value 11, in which case the condition $11 \leq 10$ is false, and execution continues in line 2.

In lightweight syntax, this would be as shown in Listing 8.3.

Listing 8.3 countWhileLightweight.fsx:

Count to 10 with a counter variable using lightweight syntax.

```
1 let mutable i = 1
2 while i <= 10 do
3     printf "%d " i
4     i <- i + 1
5 printf "\n"

1 $ fsharp --nologo countWhileLightweight.fsx
2 $ mono countWhileLightweight.exe
3 1 2 3 4 5 6 7 8 9 10
```

Notice that although the expression following the condition is preceded with a `do` keyword, and `do <expr>` is a do binding, the keyword `do` is mandatory.

Counters are so common that a special syntax has been reserved for loops using counters. These are called *for*-loops. For-loops come in several variants, and here we will focus on the one using an explicit counter. Its syntax is:

Listing 8.4: For loop.

```
1 for <ident> = <firstExpr> to <lastExpr> do <bodyExpr> [done]
```

A for-loop initially binds the counter identifier `<ident>` to be the value `<firstExpr>`. Then execution enters the body, and `<bodyExpr>` is evaluated. Once done, the counter is increased, and execution evaluates `<bodyExpr>` once again. This is repeated as long as the counter is not greater than `<lastExpr>`. As for while-loops, when using lightweight syntax the block following the `do` keyword up to and including the `done` keyword may be replaced by a newline and indentation.

The counting example from Listing 8.2 using a *for*-loop is shown in Listing 8.5

Listing 8.5 count.fsx:

Counting from 1 to 10 using a *for*-loop.

```
1 for i = 1 to 10 do printf "%d " i done
2 printfn ""

1 $ fsharp --nologo count.fsx && mono count.exe
2 1 2 3 4 5 6 7 8 9 10
```

As this interactive script demonstrates, the identifier `i` takes all the values between 1 and 10, but in spite of its changing state, it is not mutable. Note also that the return value of

Figure 8.1.: The Fibonacci spiral is an approximation of the golden spiral. Each square has side lengths of successive Fibonacci numbers, and the curve in each square is the circular arc with a radius of the square it is drawn in.

the `for` expression is “()”, like the `printf` functions. The lightweight equivalent is shown in Listing 8.6.

Listing 8.6 `countLightweight.fsx`:

Counting from 1 to 10 using a `for`-loop using the lightweight syntax.

```

1  for i = 1 to 10 do
2      printf "%d " i
3      printfn ""

1  $ fsharpc --nologo countLightweight.fsx && mono
   countLightweight.exe
2  1 2 3 4 5 6 7 8 9 10

```

To further compare `for`- and `while`-loops, consider the following problem.

Problem 8.1

Write a program that calculates the n 'th Fibonacci number.

Fibonacci numbers is a sequence of numbers starting with 1, 1, and where the next number is calculated as the sum of the previous two. Hence the first ten numbers are: 1, 1, 2, 3, 5, 8, 13, 21, 34, 55. Fibonacci numbers are related to Golden spirals shown in Figure 8.1. Often the sequence is extended with a preceding number 0, to be 0, 1, 1, 2, 3, ..., which we will do here as well.

We could solve this problem with a `for`-loop, as shown in Listing 8.7.

Listing 8.7 fibFor.fsx:

The n 'th Fibonacci number calculated using a for-loop.

```

1  let fib n =
2      let mutable pair = (0, 1)
3      for i = 2 to n do
4          pair <- (snd pair, (fst pair) + (snd pair))
5          snd pair
6
7  printfn "fib(1) = %d" (fib 1)
8  printfn "fib(2) = %d" (fib 2)
9  printfn "fib(3) = %d" (fib 3)
10 printfn "fib(10) = %d" (fib 10)

```

```

1  $ fsharp --nologo fibFor.fsx && mono fibFor.exe
2  fib(1) = 1
3  fib(2) = 1
4  fib(3) = 2
5  fib(10) = 55

```

The basic idea of the solution is that if we are given the $(n-1)$ 'th and $(n-2)$ 'th numbers, the n 'th number is trivial to compute. And assuming that `fib(1)` and `fib(2)` are given, then it is trivial to calculate `fib(3)`. For `fib(4)`, we only need `fib(3)` and `fib(2)`, hence we may disregard `fib(1)`. Thus, we realize that we can cyclicly update the previous, current, and next values by shifting values until we have reached the desired `fib(n)`. This is implemented in Listing 8.7 as the function `fib`, which takes an integer `n` as argument and returns the n 'th Fibonacci number. The function does this iteratively using a `for`-loop, where `i` is the counter value, and `pair` is the pair of the $i-1$ 'th and i 'th Fibonacci numbers. In the body of the loop, the i 'th and $i+1$ 'th numbers are assigned to `pair`. The `for`-loop automatically updates `i` for next iteration. When $n < 2$ the body of the for-loop is not evaluated, and 1 is returned. This is of course wrong for $n < 1$, but we will ignore this for now.

Listing 8.8 shows a program similar to Listing 8.7 using a while-loop instead of for-loop.

Listing 8.8 fibWhile.fsx:

The n 'th Fibonacci number calculated using a while-loop.

```

1  let fib (n : int) : int =
2      let mutable pair = (0, 1)
3      let mutable i = 1
4      while i < n do
5          pair <- (snd pair, fst pair + snd pair)
6          i <- i + 1
7      snd pair
8
9  printfn "fib(1) = %d" (fib 1)
10 printfn "fib(2) = %d" (fib 2)
11 printfn "fib(3) = %d" (fib 3)
12 printfn "fib(10) = %d" (fib 10)

```

```

1  $ fsharp --nologo fibWhile.fsx && mono fibWhile.exe
2  fib(1) = 1
3  fib(2) = 1
4  fib(3) = 2
5  fib(10) = 55

```

The programs are almost identical. In this case, the `for`-loop is to be preferred, since more lines of code typically mean more chances of making a mistake. However, while-loops are somewhat easier to argue correctness about.

The correctness of `fib` in Listing 8.8 can be proven using a *loop invariant*. An *invariant* is a statement that is always true at a particular point in a program, and a *loop invariant* is a statement which is true at the beginning and end of a loop. In line 4 in Listing 8.8, we may state the invariant: The variable `pair` is the pair of the $i - 1$ 'th and i 'th Fibonacci numbers. This is provable by induction:

Base case: Before entering the while loop, `i` is 1, `pair` is (0, 1). Thus, the invariant is true.

Induction step: Assuming that `pair` is the $i - 1$ 'th and i 'th Fibonacci numbers, the body first assigns a new value to `pair` as the i 'th and $i + 1$ 'th Fibonacci numbers, then increases `i` by one such that at the end of the loop the `pair` again contains the the $i - 1$ 'th and i 'th Fibonacci numbers.

Thus, since our invariant is true for the first case, and any iteration following an iteration where the invariant is true, is also true, then it is true for all iterations.

Thus we know that the second value in `pair` holds the value of the i 'th Fibonacci number, and since we further may prove that $i = n$ when line 7 is reached, then it is proven that `fib` returns the n 'th Fibonacci number.

While-loops also allow for logical structures other than `for`-loops, such as the case when the number of iteration cannot easily be decided when entering the loop. As an example, consider a slight variation of the above problem, where we wish to find the largest Fibonacci number less or equal some number. A solution to this problem is shown in Listing 8.9.

Listing 8.9 fibWhileLargest.fsx:

Search for the largest Fibonacci number less than a specified number.

```

1  let largestFibLeq n =
2      let mutable pair = (0, 1)
3      while snd pair <= n do
4          pair <- (snd pair, fst pair + snd pair)
5          fst pair
6
7  for i = 1 to 10 do
8      printfn "largestFibLeq(%d) = %d" i (largestFibLeq i)

```

```

1  $ fsharpc --nologo fibWhileLargest.fsx && mono
    fibWhileLargest.exe
2  largestFibLeq(1) = 1
3  largestFibLeq(2) = 2
4  largestFibLeq(3) = 3
5  largestFibLeq(4) = 3
6  largestFibLeq(5) = 5
7  largestFibLeq(6) = 5
8  largestFibLeq(7) = 5
9  largestFibLeq(8) = 8
10 largestFibLeq(9) = 8
11 largestFibLeq(10) = 8

```

The strategy here is to iteratively calculate Fibonacci numbers until we've found one larger than the argument `n`, and then return the previous. This could not be calculated with a for-loop.

8.2. Conditional Expressions

Programs often contain code which should only be executed under certain conditions. This can be expressed with `if`-expressions, whose syntax is as follows.

Listing 8.10: Conditional expressions.

```

1  if <cond> then <expr> {elif <cond> then <expr>} [else <expr>]

```

· `if`
 · `then`
 · `elif`
 · `else`

The condition `<cond>` is an expression resulting in a Boolean value, and there can be zero or more `elif` conditions, as indicated by `{}`. Each expression `<expr>` is called a *branch*, and all branches must have the same type, such that regardless of which branch is chosen, the type of the result of the conditional expression is the same. Then the expression of the first if-branch, whose condition is true, is evaluate. If all conditions are false then the `else`-branch is evaluated. If no `else` expression is present, then `()` will be returned. See Listing 8.11 for a simple example.

Listing 8.11 condition.fsx:

Conditions evaluate their branches depending on the value of the condition.

```

1  if true then printfn "hi" else printfn "bye"
2  if false then printfn "hi" else printfn "bye"
-----
1  $ fsharp --nologo condition.fsx && mono condition.exe
2  hi
3  bye

```

The lightweight syntax allows for newlines entered everywhere, but indentation must be used to express scope.

To demonstrate conditional expressions, let us write a program which writes the sentence “I have n apple(s)”, where the plural ‘s’ is added appropriately for various n ’s. This is done in Listing 8.12, using the lightweight syntax.

Listing 8.12 conditionalLightweight.fsx:

Using conditional expression to generate different strings.

```

1  let applesIHave n =
2      if n < -1 then
3          "I owe " + (string -n) + " apples"
4      elif n < 0 then
5          "I owe " + (string -n) + " apple"
6      elif n < 1 then
7          "I have no apples"
8      elif n < 2 then
9          "I have 1 apple"
10     else
11         "I have " + (string n) + " apples"
12
13  printfn "%A" (applesIHave -3)
14  printfn "%A" (applesIHave -1)
15  printfn "%A" (applesIHave 0)
16  printfn "%A" (applesIHave 1)
17  printfn "%A" (applesIHave 2)
18  printfn "%A" (applesIHave 10)
-----
1  $ fsharp --nologo conditionalLightWeight.fsx
2  $ mono conditionalLightWeight.exe
3  "I owe 3 apples"
4  "I owe 1 apple"
5  "I have no apples"
6  "I have 1 apple"
7  "I have 2 apples"
8  "I have 10 apples"

```

The sentence structure and its variants give rise to a more compact solution, since the language to be returned to the user is a variant of “I have/owe no/number apple(s)”, i.e., certain conditions determine whether the sentence should use “have” and “owe” and so forth. So, we could instead make decisions on each of these sentence parts, and then built the final sentence from its parts. This is accomplished in the following example:

Listing 8.13 conditionalLightweightAlt.fsx:

Using sentence parts to construct the final sentence.

```

1 let applesIHave n =
2     let haveOrOwe = if n < 0 then "owe" else "have"
3     let pluralS = if (n = 0) || (abs n) > 1 then "s" else ""
4     let number = if n = 0 then "no" else (string (abs n))
5
6     "I " + haveOrOwe + " " + number + " apple" + pluralS
7
8 printfn "%A" (applesIHave -3)
9 printfn "%A" (applesIHave -1)
10 printfn "%A" (applesIHave 0)
11 printfn "%A" (applesIHave 1)
12 printfn "%A" (applesIHave 2)
13 printfn "%A" (applesIHave 10)

```

```

1 $ fsharp --nologo conditionalLightWeightAlt.fsx
2 $ mono conditionalLightWeightAlt.exe
3 "I owe 3 apples"
4 "I owe 1 apple"
5 "I have no apples"
6 "I have 1 apple"
7 "I have 2 apples"
8 "I have 10 apples"

```

While arguably shorter, this solution is also denser, and most likely more difficult to debug and maintain.

Note that both `elif` and `else` branches are optional, which may cause problems. For example, both `let a = if true then 3` and `let a = if true then 3 elif false then 4` will be invalid, since F# is not smart enough to realize that the type of the expression is uniquely determined. Instead, F# looks for the `else` to ensure all cases have been covered, and that `a` always will be given a unique value of the same type regardless of the branch taken in the conditional statement. Hence, `let a = if true then 3 else 4` is the only valid expression of the 3. In practice, F# assumes that the omitted branch returns `()`, and thus it is fine to say `let a = if true then ()` and `if true then printfn "hey"`. Nevertheless, it is good practice in F# to always include an `else` branch.

8.3. Programming Intermezzo: Automatic Conversion of Decimal to Binary Numbers

Using loops and conditional expressions, we are now able to solve the following problem:

Problem 8.2

Given an integer on decimal form, write its equivalent value on the binary form.

To solve this problem, consider odd numbers: They all have the property that the least significant bit is 1, e.g., $1_2 = 1$, $101_2 = 5$, in contrast to even numbers such as $110_2 = 6$. Division by 2 is equal to right-shifting by 1, e.g., $1_2/2 = 0.1_2 = 0.5$, $101_2/2 = 10.1_2 =$

$2.5, 110_2/2 = 11_2 = 3$. Thus, through dividing by 2 and checking the remainder, we may sequentially read off the least significant bit. This leads to the algorithm shown in Listing 8.14.

Listing 8.14 dec2bin.fsx:

Using integer division and remainder to write any positive integer in binary form.

```

1  let dec2bin n =
2      if n < 0 then
3          "Illegal value"
4      elif n = 0 then
5          "0b0"
6      else
7          let mutable v = n
8          let mutable str = ""
9          while v > 0 do
10             str <- (string (v % 2)) + str
11             v <- v / 2
12             "0b" + str
13
14
15  printfn "%4d -> %s" -1 (dec2bin -1)
16  printfn "%4d -> %s" 0 (dec2bin 0)
17  for i = 0 to 3 do
18      printfn "%4d -> %s" (pown 10 i) (dec2bin (pown 10 i))

```

```

1  $ fsharpc --nologo dec2bin.fsx && mono dec2bin.exe
2      -1 -> Illegal value
3      0 -> 0b0
4      1 -> 0b1
5      10 -> 0b1010
6      100 -> 0b1100100
7      1000 -> 0b1111101000

```

In the code, the states `v` and `str` are iteratively updated until `str` finally contains the desired solution.

To prove that Listing 8.14 calculates the correct sequence, we use induction. First we realize that for $v < 1$, the while-loop is skipped, and the result is trivially true. We will concentrate on line 9 in Listing 8.14 and will prove the following loop invariant: The string `str` contains all the bits of `n` to the right of the bit pattern remaining in variable `v`.

Base case $n = 000 \dots 000x$: If n only uses the lowest bit, then $n = 0$ or $n = 1$. If $n = 0$, then it is trivially correct. Considering the case $n = 1$: Before entering into the loop, `v` is 1, and `str` is the empty string, so the invariant is true. The condition of the while-loop is $1 > 0$, so execution enters the loop. Since integer division of 1 by 2 gives 0 with remainder 1, `str` is set to `"1"` and `v` to 0. Now we reexamine the while-loop's condition, $0 > 0$, which is false, so we exit the loop. At this point, `v` is 0 and `str` is `"1"`, so all bits have been shifted from `n` to `str`, and none are left in `v`. Thus the invariant is true. Finally, the program returns `"0b1"`.

Induction step: Consider the case of $n > 1$, and assume that the invariant is true when entering the loop, i.e., that m bits already have been shifted to `str` and that $n > 2^m$.

8. Controlling Program Flow

In this case, v contains the remaining bits of n , which is the integer division $v = n / 2^{**m}$. Since $n > 2^m$, v is non-zero, and the loop condition is true, so we enter the loop body. In the loop body we concatenate the rightmost bit of v to the left of str using $v \% 2$, and right-shift v one bit to the right with $v <- v / 2$. Thus, when returning to the condition the invariant is true, since the right-most bit in v has been shifted to str . This continues until all bits have been shifted to str and $v = 0$, in which case the loop terminates, and `"0b"+str` is returned.

Thus we have proven that `dec2bin` correctly converts integers to strings representing binary numbers.

A | The Console in Windows, MacOS X, and Linux

Almost all popular operating systems are accessed through a user-friendly *graphical user interface (GUI)* that is designed to make typical tasks easy to learn to solve. As a computer programmer, you often need to access some of the functionalities of the computer, which, unfortunately, are sometimes complicated by this particular graphical user interface. The *console*, also called the *terminal* and the *Windows command line*, is the right hand of a programmer. The console is a simple program that allows you to complete text commands. Almost all the tasks that can be done with the graphical user interface can be done in the console and vice versa. Using the console, you will benefit from its direct control of the programs we write, and in your education, you will benefit from the fast and raw information you get through the console.

A.1. The Basics

When you open a *directory* or *folder* in your preferred operating system, the directory will have a location in the file system, whether from the console or through the operating system's graphical user interface. The console will almost always be associated with a particular directory or folder in the file system, and it is said that it is the directory that the console is in. The exact structure of file systems varies between Linux, MacOS X, and Windows, but common is that it is a hierarchical structure. This is illustrated in Figure A.1.

- directory
- folder

There are many predefined console commands, available in the console, and you can also make your own. In the following sections, we will review the most important commands in the three different operating systems. These are summarized in Table A.1.

A.2. Windows

In this section we will discuss the commands summarized in Table A.1. Windows 7 and earlier versions: To open the console, press **Start->Run** in the lower left corner, and then type **cmd** in the box. In Windows 8 and 10, you right-click on the windows icon, choose **Run** or equivalent in your local language, and type **cmd**. Alternatively, you can type **Windows-key + R**. Now you should open a console window with a prompt showing something like Listing A.1.

Figure A.1.: The top file hierarchy levels of common operating systems.

Windows	MacOS X/Linux	Description
<code>dir</code>	<code>ls</code>	Show content of present directory.
<code>cd <dir></code>	<code>cd <dir></code>	Change present directory to <code><dir></code> .
<code>mkdir <dir></code>	<code>mkdir <dir></code>	Create directory <code><dir></code> .
<code>rmdir <dir></code>	<code>rmdir <dir></code>	Delete <code><dir></code> (Warning: cannot be reverted).
<code>move <file> <file or dir></code>	<code>mv <file> <file or dir></code>	Move <code><fil></code> to <code><file or dir></code> .
<code>copy <file1> <file2></code>	<code>cp <file1> <file2></code>	Create a new file called <code><file2></code> as a copy of <code><file1></code> .
<code>del <file></code>	<code>rm <file></code>	delete <code><file></code> (Warning: cannot be reverted).
<code>echo <string or variable></code>	<code>echo <string or variable></code>	Write a string or content of a variable to screen.

The commands available from the console must be in its *search path*. The search path can be seen using `echo`, as shown in Listing A.8.

Listing A.8: Displaying the search path.

```

1 C:\Users\sporrington\Documents>echo %Path%
2 C:\Windows\system32;C:\Windows;C:\Windows\System32\Wbem;

   Files\emacs-24.5\bin\"
3
4 C:\Users\sporrington\Documents>

```

The path can be changed using the Control panel in the graphical user interface. In Windows 7, choose the Control panel, choose **System and Security** → **System** → **Advanced system settings** → **Environment Variables**. In Windows 10, you can find this window by searching for “Environment” in the Control panel. In the window’s **System variables** box, double-click on **Path** and add or remove a path from the list. The search path is a list of paths separated by “;”. Beware, Windows uses the search path for many different tasks, so remove only paths that you are certain are not used for anything.

A useful feature of the console is that you can use the **tab**-key to cycle through filenames. E.g., if you write `cd` followed by a space and **tab** a couple of times, then the console will suggest to you the available directories.

A.3. MacOS X and Linux

MacOS X (OSX) and Linux are very similar, and both have the option of using *bash* as console. It is in the standard console on MacOS X and on many Linux distributions. A summary of the most important *bash* commands is shown in Table A.1. In MacOS X,

you find the console by opening **Finder** and navigating to **Applications** → **Utilities** → **Terminal**. In Linux, the console can be started by typing **Ctrl + Alt + T**. Some Linux distributions have other key-combinations such as **Super + T**.

Once opened, the console is shown in a window with content, as shown in Listing A.9.

Listing A.9: The MacOS console.

“FN11194” is the name of the computer, the character `~` is used as an alias for the user’s home directory, and “sporring” is the username for the user presently logged onto the system. Use `ls` to see which files are present, as shown in Listing A.10.

The flag `-l` means long, and many other flags can be found by querying the built-in manual with `man ls`. The output is divided into columns, where the left column shows a number of codes: “d” stands for directory, and the set of three of optional “rwx” denote whether respectively the owner, the associated group of users, and anyone can respectively “r” - read, “w” - write, and “x” - execute the file. In all directories but the **Public** directory, only the owner can do any of the three. For directories, “x” means permission to enter. The second column can often be ignored, but shows how many links there are to the file or directory. Then follows the username of the owner, which in this case is **sporring**. The files are also associated with a group of users, and in this case, they all are associated with the group called **staff**. Then follows the file or directory size, the date of last change, and the file or directory name. There are always two hidden directories: “.” and “..”, where “.” is an alias for the present directory, and “..” for the directory above. Hidden files will be shown with the `-a` flag.

Use `cd` to change to the directory, for example to `Documents` as shown in Listing A.12. · `cd`

Listing A.12: Change directory with `cd`.

```
1 FN11194:~ sporring$ cd Documents/

Note that some graphical user interfaces translate standard filenames and directories to the local language, such that navigating using the graphical user interface will reveal other files and directories, which, however, are aliases.

You can create a new directory using `mkdir`, as demonstrated in Listing A.13. · `mkdir`

Listing A.15: Moving files with `mv`.

```
1 FN11194:Documents sporring$ echo mv hi.txt myFolder/

4 FN11194:Documents sporring$ rmdir myFolder/  
5 FN11194:Documents sporring$ ls  
6 FN11194:Documents sporring$
```

Only commands found on the *search-path* are available in the console. The content of the · *search-path*
search-path is seen using the `echo` command, as demonstrated in Listing A.17.

Listing A.17: The content of the search-path.

```
1 FN11194:Documents sporring$ echo $PATH
2 /Applications/Maple
   17//Applications/PackageManager.app/Contents/MacOS/:
   /Applications/MATLAB_R2014b.app/bin/:/opt/local/bin:
   /opt/local/sbin:/usr/local/bin:/usr/bin:/bin:/usr/sbin:
   /sbin:/opt/X11/bin:/Library/TeX/texbin
3 FN11194:Documents sporring$
```

The search-path can be changed by editing the setup file for Bash. On MacOS X it is called `~/.profile`, and on Linux it is either `~/.bash_profile` or `~/.bashrc`. Here new paths can be added by adding the following line: `export PATH=<new path>:<another new path>:$PATH`.

A useful feature of Bash is that the console can help you write commands. E.g., if you write `fs` followed by pressing the `tab`-key, and if `Mono` is in the search-path, then Bash will typically respond by completing the line as `fsharp`, and by further pressing the `tab`-key some times, Bash will show the list of options, typically `fshpari` and `fsharpc`. Also, most commands have an extensive manual which can be accessed using the `man` command. E.g., the manual for `rm` is retrieved by `man rm`.

B.1. Binary Numbers

Humans like to use the *decimal number* system for representing numbers. Decimal numbers are *base 10* meaning that a decimal number consists of a sequence of digits separated by a *decimal point*, where each *digit* can have values $d \in \{0, 1, 2, \dots, 9\}$ and the weight of each digit is proportional to its place in the sequence of digits with respect to the decimal point, i.e., the number $357.6 = 3 \cdot 10^2 + 5 \cdot 10^1 + 7 \cdot 10^0 + 6 \cdot 10^{-1}$, or in general, for a number consisting of digits d_i with $n + 1$ and m digits to the left and right of the decimal point, the value v is calculated as:

$$v = \sum_{i=-m}^n d_i 10^i. \quad (\text{B.1})$$

The basic unit of information in almost all computers is the binary digit, or *bit* for short. A *binary number* consists of a sequence of binary digits separated by a decimal point, where each digit can have values $b \in \{0, 1\}$, and the base is 2. The general equation is,

$$v = \sum_{i=-m}^n b_i 2^i, \quad (\text{B.2})$$

and examples are $1011.1_2 = 1 \cdot 2^3 + 0 \cdot 2^2 + 1 \cdot 2^1 + 1 \cdot 2^0 + 1 \cdot 2^{-1} = 11.5$. Notice that we use subscript 2 to denote a binary number, while no subscript is used for decimal numbers. The left-most bit is called the *most significant bit*, and the right-most bit is called the *least significant bit*. Due to typical organisation of computer memory, 8 binary digits is called a *byte*, and the term *word* is not universally defined but typically related to the computer architecture, a program is running on, such as 32 or 64 bits.

Other number systems are often used, e.g., *octal numbers*, which are base 8 numbers and have digits $o \in \{0, 1, \dots, 7\}$. Octals are useful short-hand for binary, since 3 binary digits map to the set of octal digits. Likewise, *hexadecimal numbers* are base 16 with digits $h \in \{0, 1, 2, 3, 4, 5, 6, 7, 8, 9, a, b, c, d, e, f\}$, such that $a_{16} = 10$, $b_{16} = 11$ and so on. Hexadecimals are convenient, since 4 binary digits map directly to the set of hexadecimal digits. Thus $367 = 101101111_2 = 557_8 = 16f_{16}$. A list of the integers 0–63 in various bases is given in Table B.1.

is infinite in size both in the sense that there is no largest nor smallest number, and that between any 2 given numbers there are infinitely many numbers. Reals are widely used for calculation, but since any computer only has finite memory, there are infinitely many numbers which cannot be represent on a computer. Hence, any computation performed on a computer with reals must rely on approximations. *IEEE 754 double precision floating-point format (binary64)*, known as a *double*, is a standard for representing an approximation of reals using 64 bits. These bits are divided into 3 parts: sign, exponent and fraction,

$$s\ e_1e_2\ldots e_{11}\ m_1m_2\ldots m_{52},$$

- IEEE 754 double precision floating-point format
- binary64

B. Number Systems on the Computer

where s , e_i , and m_j are binary digits. The bits are converted to a number using the equation by first calculating the exponent e and the mantissa m ,

$$e = \sum_{i=1}^{11} e_i 2^{11-i}, \quad (\text{B.3})$$

$$m = \sum_{j=1}^{52} m_j 2^{-j}. \quad (\text{B.4})$$

I.e., the exponent is an integer, where $0 \leq e < 2^{11}$, and the mantissa is a rational, where $0 \leq m < 1$. For most combinations of e and m , the real number v is calculated as,

$$v = (-1)^s (1 + m) 2^{e-1023} \quad (\text{B.5})$$

with the exceptions that

	$m = 0$	$m \neq 0$
$e = 0$	$v = (-1)^s 0$ (signed zero)	$v = (-1)^s m 2^{1-1023}$ (subnormals)
$e = 2^{11} - 1$	$v = (-1)^s \infty$	$v = (-1)^s \text{NaN}$ (not a number)

where $e = 2^{11} - 1 = 11111111111_2 = 2047$. The largest and smallest number that is not infinity is thus

$$e = 2^{11} - 2 = 2046, \quad (\text{B.6})$$

$$m = \sum_{j=1}^{52} 2^{-j} = 1 - 2^{-52} \simeq 1, \quad (\text{B.7})$$

$$v_{\max} = \pm (2 - 2^{-52}) 2^{1023} \simeq \pm 2^{1024} \simeq \pm 10^{308}. \quad (\text{B.8})$$

The density of numbers varies in such a way that when $e - 1023 = 52$, then

$$v = (-1)^s \left(1 + \sum_{j=1}^{52} m_j 2^{-j} \right) 2^{52} \quad (\text{B.9})$$

$$= \pm \left(2^{52} + \sum_{j=1}^{52} m_j 2^{-j} 2^{52} \right) \quad (\text{B.10})$$

$$= \pm \left(2^{52} + \sum_{j=1}^{52} m_j 2^{52-j} \right) \quad (\text{B.11})$$

$$\stackrel{k=52-j}{=} \pm \left(2^{52} + \sum_{k=51}^0 m_{52-k} 2^k \right), \quad (\text{B.12})$$

which are all integers in the range $2^{52} \leq |v| < 2^{53}$. When $e - 1023 = 53$, then the same calculation gives

$$v \stackrel{k=53-j}{=} \pm \left(2^{53} + \sum_{k=52}^1 m_{53-k} 2^k \right), \quad (\text{B.13})$$

which are every second integer in the range $2^{53} \leq |v| < 2^{54}$, and so on for larger values of e . When $e - 1023 = 51$, the same calculation gives,

$$v \stackrel{k=51-j}{=} \pm \left(2^{51} + \sum_{k=50}^{-1} m_{51-k} 2^k \right), \quad (\text{B.14})$$

B. Number Systems on the Computer

which is a distance between numbers of $1/2$ in the range $2^{51} \leq |v| < 2^{52}$, and so on for smaller values of e . Thus we may conclude that the distance between numbers in the interval $2^n \leq |v| < 2^{n+1}$ is 2^{n-52} , for $-1022 = 1 - 1023 \leq n < 2046 - 1023 = 1023$. For subnormals, the distance between numbers is

$$v = (-1)^s \left(\sum_{j=1}^{52} m_j 2^{-j} \right) 2^{-1022} \quad (\text{B.15})$$

$$= \pm \left(\sum_{j=1}^{52} m_j 2^{-j} 2^{-1022} \right) \quad (\text{B.16})$$

$$= \pm \left(\sum_{j=1}^{52} m_j 2^{-j-1022} \right) \quad (\text{B.17})$$

$$\stackrel{k=-j-1022}{=} \pm \left(\sum_{j=-1023}^{-1074} m_{-k-1022} 2^k \right), \quad (\text{B.18})$$

which gives a distance between numbers of $2^{-1074} \simeq 10^{-323}$ in the range $0 < |v| < 2^{-1022} \simeq 10^{-308}$.

C | Commonly Used Character Sets

Letters, digits, symbols, and space are the core of how we store data, write programs, and communicate with computers and each other. These symbols are in short called characters and represent a mapping between numbers, also known as codes, and a pictorial representation of the character. E.g., the ASCII code for the letter 'A' is 65. These mappings are for short called character sets, and due to differences in natural languages and symbols used across the globe, many different character sets are in use. E.g., the English alphabet contains the letters 'a' to 'z'. These letters are common to many other European languages which in addition use even more symbols and accents. For example, Danish has further the letters 'æ', 'ø', and 'å'. Many non-European languages have completely different symbols, where the Chinese character set is probably the most extreme, and some definitions contain 106,230 different characters, albeit only 2,600 are included in the official Chinese language test at the highest level.

Presently, the most common character set used is Unicode Transformation Format (UTF), whose most popular encoding schemes are 8-bit (UTF-8) and 16-bit (UTF-16). Many other character sets exist, and many of the later build on the American Standard Code for Information Interchange (ASCII). The ISO-8859 codes were an intermediate set of character sets that are still in use, but which is greatly inferior to UTF. Here we will briefly give an overview of ASCII, ISO-8859-1 (Latin1), and UTF.

C.1. ASCII

The *American Standard Code for Information Interchange* (ASCII) [8], is a 7 bit code tuned for the letters of the English language, numbers, punctuation symbols, control codes and space, see Tables C.1 and C.2. The first 32 codes are reserved for non-printable control characters to control printers and similar devices or to provide meta-information. The meaning of each control character is not universally agreed upon.

- American Standard Code for Information Interchange
- ASCII

The code order is known as *ASCIIbetical order*, and it is sometimes used to perform arithmetic on codes, e.g., an uppercase letter with code c may be converted to lower case by adding 32 to its code. The ASCIIbetical order also has a consequence for sorting, i.e., when sorting characters according to their ASCII code, 'A' comes before 'a', which comes before the symbol '{'.

C.2. ISO/IEC 8859

The ISO/IEC 8859 report http://www.iso.org/iso/catalogue_detail?csnumber=28245 defines 10 sets of codes specifying up to 191 codes and graphics characters using 8 bits. Set 1, also known as ISO/IEC 8859-1, Latin alphabet No. 1, or *Latin1*, covers many European languages and is designed to be compatible with ASCII, such that code for the printable characters in ASCII is the same in ISO 8859-1. Table C.3 shows the characters above 7e. Codes 00-1f and 7f-9f are undefined in ISO 8859-1.

C.3. Unicode

Unicode is a character standard defined by the Unicode Consortium, <http://unicode.org>, as the *Unicode Standard*. Unicode allows for 1,114,112 different codes. Each code is called a *code point* which represents an abstract character. However, not all abstract characters require a unit of several code points to be specified. Code points are divided into 17 planes, each with $2^{16} = 65,536$ code points. Planes are further subdivided into named *blocks*. The first plane is called the *Basic Multilingual plane* and its block of the first 128 code points is called the *Basic Latin block* and is identical to ASCII, see Table C.1, and code points 128-255 are called the *Latin-1 Supplement block*, and are identical to the upper range of ISO 8859-1, see Table C.3. Each code-point has a number of attributes such as the *Unicode general category*. Presently more than 128,000 code points are defined as covering 135 modern and historical writing systems, and obtained at <http://www.unicode.org/Public/UNIDATA/UnicodeData.txt>, which includes the code point, name, and general category.

A Unicode code point is an abstraction from the encoding and the graphical representation of a character. A code point is written as “U+” followed by its hexadecimal number, and for the Basic Multilingual plane, 4 digits are used, e.g., the code point with the unique name LATIN CAPITAL LETTER A has the Unicode code point “U+0041”, and is in this

text visualized as 'A'. More digits are used for code points of the remaining planes.

The general category is used to specify valid characters that do not necessarily have a visual representation but possibly transform text. Some categories and their letters in the first 256 code points are shown in Table C.5.

To store and retrieve code points, they must be encoded and decoded. A common encoding is *UTF-8*, which encodes code points as 1 to 4 bytes, and which is backward-compatible with ASCII and ISO 8859-1. Hence, in all 3 coding systems, the character with code 65 represents the character 'A'. Another popular encoding scheme is *UTF-16*, which encodes characters as 2 or 4 bytes, but which is not backward-compatible with ASCII or ISO 8859-1. UTF-16 is used internally in many compilers, interpreters, and operating systems.
