Chapter 2

Introduction

Programming is the act of solving a problem by writing a program to be executed on a computer. A general method for solving problems was given by George Pólya [5] and adapted to programming is:

Understand the problem: To solve any problem it is crucial that the problem formulation is understood, and questions like: What is to be solved? Do you understand everything in the problem description. Is all information for finding the solution available or is something missing?

Design a plan: Good designs means that programs are faster to program easier to debug and maintain. So before you start typing a program consider things like: What are the requirements and constraints for the program? Which components should the program have? How are these components to work together? Designing often involves drawing a diagram of the program, and writing pseudo-code on paper.

Implement the plan: Implementation is the act of transforming a program design into a code. A crucial part of any implementation is choosing which programming language to use. Also, the solution to many problems will have a number of implementations which vary in how much code they require, to which degree they rely on external libraries, which programming style the are best suited for, what machine resources they require, and what their running times are. With a good design, then the coding is usually easy, since the design will have uncovered the major issues and found solutions for these, but sometimes implementation reveals new problems, which requires rethinking the design. Most implementations also include writing documentation of the code.

Reflect on the result: A crucial part in any programming task is ensuring that the program solves the problem sufficiently. E.g., what are the program's bugs, is the documentation of the code sufficient and relevant for its intended use. Is the code easily maintainable and extendable by other programmers. Are there any general lessons to be learned from or general code developed by the programming experience, which may be used for future programming sessions?

Programming is a very complicated process, and the steps in Pólya's list are almost always to be performed, but the order of the steps and the number of times each step is performed varies. [1]
This book focusses on 3 fundamentally different approaches to programming:

· Imperative programming

Imperative programming, which is a type of programming that *statements* to change the program's *state*. Imperative programming emphasises *how a program shall accomplish a solution* and less on *what the solution is*. A cooking recipes is an example of the spirit of imperative programming. Almost all computer hardware is designed to execute low-level programs written in imperative style. The first major language was FORTRAN [2] which emphasized imperative style of programming.

· statements
· state

· Declarative programming

---

[1]**Should we mention core activities: Requirements, Design, Construction, Testing, Debugging, Deployment, Maintenance?**

Declarative programming, which emphasises *what a program shall accomplish* but not *how*. We will consider Functional programming as a type of declarative programming. A type of programming which evaluates *functions* and avoids state changes. The program consists of *expressions* instead of statements. As a consequence, the output of functions only depends on its arguments. Functional programming has its roots in lambda calculus [1], and the first language emphasizing functional programming was Lisp [3].

Structured programming, , which emphasises organisation of code in units with well defined interfaces and isolation of internal states and code from other parts of the program. We will focus on Object-oriented programming is the example of structured programming. is a type of programming, where the states and programs are structured into *objects*. A typical object-oriented design takes a problem formulation and identifies key nouns as potential objects and verbs as potential actions to be take on objects. The first object-oriented programming language was Simula 67 developed by Dahl and Nygaard at the Norwegian Computing Center in Oslo.

Most programs follows a single programming paradigm as, e.g., one of the above, but are a mix. Nevertheless, this book will treat each paradigm separately to emphasize their advantages and disadvantages.

This book uses F# also known as Fsharp, which is a functional first programming language that also supports imperativ and object oriented programming. It was originally developed for Microsoft's .Net platform, but is available as open source for many operating systems through Mono. As an introduction to programming, F# is a young programming language still under development, with syntax that at times is a bit complex, but it offers a number of advantages:

Interactive and compile mode F# has an interactive and a compile mode of operation.

Indentation for scope F# uses indentation to indicate scope.

Strongly typed F# is strongly typed, reducing the number of run-time errors.

Multi-platform F# is available on Linux, Mac OS X, Android, iOS, Windows, GPUs, and browsers via the Mono platform.

Free to use and open source F# is supported by the Fsharp foundation (`http://fsharp.org`) and sponsored by Microsoft.

Assemblies F# programs interface easily with other .Net and Mono programs through the language-independent, platform-independent bytecode called Common Intermediate Language (CIL).

Modern computing F# supports all aspects of modern computing including Graphical User Interfaces, Web programming, Information rich programming, Parallel algorithms, . . .

Integrated development environments (IDE) F# is supported by major IDEs such as Visual Studio (`https://www.visualstudio.com`) and Xamarin Studio (`https://www.xamarin.com`).

Learning to program requires mastering a programming language, however most programming languages contains details that are rarely used or used in contexts far from a specific programming topic. Hence, this book takes the approach to start with an introduction to the most basic concepts of F# in Part I, followed by the 3 programming paradigms in Part II–IV while gradually expanding the introduction of F# syntax and semantics. In Part V are a number of general topics given for reference. The disadvantage of this approach is that no single part contains a reference guide to F# and F# topics are revisited and expanded across the book. For further reading please consult `http://fsharp.org`.

Part I

F# basics

Chapter 3

Executing F# code

3.1 Source code

F# is a functional first programming language that also supports imperativ and object oriented programming. It also has strong support for parallel programming and information rich programs. It was originally developed for Microsoft's .Net platform, but is available as open source for many operating systems through Mono. In this text we consider F# 4.0 and its Mono implementation, which is different from .Net mainly in terms of the number of libraries accessible. The complete language specification is described in `http://fsharp.org/specs/language-spec/4.0/FSharpSpec-4.0-latest.pdf`.

F# has 2 modes of execution, *interactive* and *compiled*. Interactive mode is well suited for small experiments or back-of-an-envelope calculations, but not for programming in general. In Mono, the interactive system is started by calling `fsharpi` from the *console*, while compilation is performed with `fshparc` and execution of the compiled code is performed using the `mono` command. The various forms of fsharp programs are identified by suffixes:

`.fs` An *implementation file*

`.fsi` A *signature file*

`.fsx` A *script file*

`.fscript` Same as `.fsx`

`.exe` An *executable file*

The implementation, signature, and script files are all typically compiled to produce an executable file, but syntactical correct code can also be entered into the interactive system, in which case these are called *script-fragments*. The implementation and signature files are special kinds of script files used for building *modules*.

3.2 Executing programs

Programs may either be executed by the interpreter or by compiling and executing the compiled code. In `Mono` the interpreter is called `fsharpi` and can be used in 2 ways: interactively, where a user enters 1 or more script-fragments separated by the `";;"` token, or to execute a script file treated as a single script-fragment. To illustrate the difference, consider the following program, which declares a value `a` to be the decimal value 3.0 and finally print it to the console:

```
let a = 3.0
printfn "%g" a
```

An interactive session is obtained by starting the console, typing the `fsharpi` command, typing the lines of the program, and ending the script-fragment with the `";;"` token:

```
$ fsharpi

F# Interactive for F# 4.0 (Open Source Edition)
Freely distributed under the Apache 2.0 Open Source License

For help type #help;;

> let a = 3.0
- printfn "%g" a;;
3

val a : float = 3.0
val it : unit = ()

> #quit;;
```

The interpreter is stopped by pressing `ctrl-d` or typing `"#quit;;"`. Conversely, executing the file with the interpreter as follows,

```
$ fsharpi gettingStartedStump.fsx
3
```

Finally, compiling and executing the code is performed as,

```
$ fsharpc gettingStartedStump.fsx
F# Compiler for F# 4.0 (Open Source Edition)
Freely distributed under the Apache 2.0 Open Source License
$ mono gettingStartedStump.exe
3
```

Both the interpreter and the compiler translates the source code into a format, which can be executed by the computer. While the compiler performs this translation once and stores the result in the executable file, the interpreter translates the code every time the code is executed. Thus, to run the program again with the interpreter, then it must be retranslated as `"$fsharpi gettingStartedStump.fsx"`, but since the program has been compiled, then the compile-execute only needs the be re-executed `"$ mono gettingStartedStump.exe"`. On a Macbook Pro, with a 2.9 Ghz Intel Core i5, the time the various stages takes for this script are.

Command	Time
`fsharpi gettingStartedStump.fsx`	1.88s
`fsharpc gettingStartedStump.fsx`	1.90s
`mono randomTextOrder0.exe`	0.05s

I.e., executing the script with `fsharpi` is slightly faster than by first compiling it with `fsharpc` and then executing the result with `mono`, $1.88s < 0.05s + 1.90s$, if the script were to be executed only once, but every future execution of the script using the compiled version requires only the use of `mono`, which is much faster than `fsharpi`, $1.88s \gg 0.05s$.
[1]

The interactive session results in extra output on the *type inference* performed, which is very useful for *debugging* and development of code-fragments, but both executing programs with the interpreted directly from a file and compiling and executing the program is much preferred for programming complete programs, since the starting state is well defined, and since this better supports *unit-testing* a method for debugging programs.

· type inference

· debugging

· unit-testing

---

[1]**Remember to add something about the `it` value in interactive mode.**

Chapter 4

Quick-start guide

Programming is the art of solving problems by writing a program to be executed by a computer. For example, to solve the following problem,

What is the sum of 357 and 864?

we have written the following program in F#,

```
let a = 357
let b = 864
let c = a + b
printfn "%A" c
```

```
1221
```

Listing 4.1: quickStartSum.fsx - A script to add 2 numbers and print the result to the console.

In box the above, we see our program was saved as a script in a file called `quickStartSum.fsx`, and in the console we executed the program by typing the command `fsharpi quickStartSum.fsx`. The result is then printed in the console to be `1221`.

To solve the program we made program consisting of several lines, where each line was a *statement*. The first statement `let a = 357` used the *let keyword* to *bind* the value 357 to the name `a`. Likewise, we bound the value 864 to the name `b`, but to the name `c` we bound the result of evaluating the *expression* `a + b`. That is, first the value `a + b` was calculated by substituting the names of `a` and `b` with their values to give the expression, `357 + 864`, then this expression was evaluated by adding the values to give, `1221`, and this value was finally bound to the name `c`. The last line printed the value of `c` to the console followed by a LF (line feed, see Appendix B.1) with the `printfn` function. Here `printfn` is a function of 2 arguments: `"%A"` and `c`. Notice, that in contrast to many other languages, F# does not use parentheses to frame the list of arguments, nor does it use commas to separate them. In general, the `printfn` function always has 1 or more arguments, and the first is a *format string*. A *string* is a sequence of characters starting and ending with double quotation marks. E.g., `let s = "this is a string of characters"` binds the string `"this is..."` to the name `s`. For the `printfn` function, the format string may be any string, but if it contains format character sequences, such as `%A`, then the values following the format string are substituted. The format string must match the value *type*, that is, here `c` is of type integer, whereas the format string `%A` matches any type.

Types are a central concept in F#. In the script 4.1 we bound values of types `int` and `string` to names. The values were not *declared* to have these types, instead the types were *inferred* by F#. Had we typed these statements line by line in an interactive session, then we would have seen the inferred types:

· statement
· `let`
· keyword
· binding
· expression

· format string
· string

· type

· type declaration
· type inference

```
> let a = 357;;
```

```
val a : int = 357

> let b = 864;;

val b : int = 864

> let c = a + b;;

val c : int = 1221

> printfn "%A" c;;
1221
val it : unit = ()
```

Listing 4.2: fsharpi

The an interactive session displays the type using the *val* keyword. Since the value is also responded,   · val
then the last `printfn` statement is superfluous. However, it is ill adviced to design programs to be
run in an interactive session, since the scripts needs to be manually copied every time it is to be run,
and since the starting state may be unclear.   Advice!
Were we to solve a slightly different problem,

> What is the sum of 357.6 and 863.4?

then we would have to use floating point arithmatic instead of integers, and the program would look
like,

```
let a = 357.6
let b = 863.4
let c = a + b
printfn "%A" c
```

```
1221.0
```

Listing 4.3: quickStartSumFloat.fsx - Floating point types and arithmatic.

On the surface, this could appear as an almost negligible change, but the set of integers and the set of
real numbers (floats) require quite different representations, in order to be effective on a computer, and
as a consequence, the implementation of their operations such as addition are very different. Thus,
although the response is an integer, it has type `float`, which is indicated by `1221.0` which is not the
same as `1221`. F# is very picky about types, and generally does not allow types to be mixed. E.g., in
an interactive session,

```
> let a = 357;;

val a : int = 357

> let b = 863.4;;

val b : float = 863.4

> let c = a + b;;

  let c = a + b;;
  ------------^

/Users/sporring/Desktop/fsharpNotes/stdin(3,13): error FS0001: The type 'float' does not match t
```

Listing 4.4: fsharpi

|	
``` let a = 357 let a = 864;; ```	``` let a = 357;; let a = 864;; ```
(a) Illegal	(b) Legal

Figure 4.1: Binding of the the same name in the same scope is illegal in F# 2, but legal in a different scopes. In (a) the two bindings are in the same scope, which is illegal, while in (b) the bindings are in separate scopes by the extra ;; token, which is legal.

we see that binding a name to a number without a decimal point is inferred to be integer, while when binding to a number with a decimal point, then the type is inferred to be a float, and when trying to add values of integer and floating point, then we get an error.

F# is a functional first programming language, and one implication is that names are constant and cannot be changed. If attempted, then F# will return an error as, e.g.,

```
let a = 357
let a = 864
```

```
/Users/sporring/repositories/fsharpNotes/src/quickStartRebindError.fsx(2,5): error FS0037: Dupli
```

Listing 4.5: quickStartRebindError.fsx - A name cannot be rebound.

However, if the same was performed in an interactive session,

```
> let a = 357;;

val a : int = 357

> let a = 864;;

val a : int = 864
```

Listing 4.6: fsharpi

then apparently rebinding is legal. The difference is that the *;; token* defines a new nested *scope*.[1] A token is a letter or a word, which the F# considers as an atomic unit. A scope is an area in a program, where a binding is valid. Scopes can be *nested*, and in F# a binding may reuse names in a nested scope, in which case the previous value is *overshadowed*. I.e., attempting the same without ;; between the two let statements results in an error, e.g.,

· ;;
· token
· scope
· nested scope
· overshadow

```
> let a = 357
- let a = 864;;

  let a = 864;;
  ----^

/Users/sporring/Desktop/fsharpNotes/stdin(2,5): error FS0037: Duplicate definition of value 'a'
```

Listing 4.7: fsharpi

Scopes can be visualized as nested squares as shown in Figure 4.1.

In F# *functions* are also values, and defining a function `sum` as part of the solution to the above program gives,

· function

```
let sum x y = x + y
let c = sum 357 864
printfn "%A" c
```

---

[1]**Language change: Spec 4.0 p. 15.1 talks about blocks instead of scopes.**

```
1221
```

Listing 4.8: quickStartSumFct.fsx - A script to add 2 numbers using a user defined function.

Entering the function into an interactive session will illustrate the inferred type, the function `sum` has: `val sum : x:int * y:int -> int`, by which is meant that `sum` is a mapping from the set product of integers with integers into integers. Type inference in F# may cause problems, since the type of a function is inferred in the context, in which it is defined. E.g., in an interactive session, defining the sum in one scope on a single line will default the types to integers, F#'s favorite type, which will give an error, if it in a nested scope is to be used for floats,

```
> let sum x y = x + y;;

val sum : x:int -> y:int -> int

> let c = sum 357.6 863.4;;

  let c = sum 357.6 863.4;;
  ------------^^^^^

/Users/sporring/Desktop/fsharpNotes/stdin(2,13): error FS0001: This expression was expected to h
    int
but here has type
    float
```

Listing 4.9: fsharpi

A remedy is to either define the function in the same scope as its use,

```
> let sum x y = x + y
- let c = sum 357.6 863.4;;

val sum : x:float -> y:float -> float
val c : float = 1221.0
```

Listing 4.10: fsharpi

In this chapter, we have scratched the surface of learning how to program by concentrating on a number of key programming concepts and how they are expressed in the F# language. In the following chapters, we will expand the description of F# with features used in all programming approaches.

Chapter 5

Constants, tuples, and types

All programs rely on processing of data, and an essential property of data is its *type*. A *literal* is a fixed value such as "3", and if we type the number 3 in an interactive session at the input prompt, then F# responds as follows,

· type
· literal

```
> 3;;
val it : int = 3
```
Listing 5.1: fsharpi, Typing the number 3.

What this means is that F# has inferred the type to be *int* and bound it to the identifier *it*. Rumor has it, that the identifier it is an abbreviation for 'irrelevant'. For more on binding and identifiers see Chapter 6. Types matter, since the operations that can be performed on integers are quite different from those that can be performed on, e.g., strings. I.e.,

· int
· it

```
> 3;;
val it : int = 3
> 3.0;;
val it : float = 3.0
> '3';;
val it : char = '3'
> "3";;
val it : string = "3"
```
Listing 5.2: fsharpi, Many representations of the number 3 but using different types.

Each literal represent the number 3, but their types are different, and hence they are quite different values. The types int for integer numbers, float for floating point numbers, char for characters, and string for strings of characters are the most common types of literals. A table of all predefined types is given in Table 5.1.[1] Besides these built-in types, F# is designed such that it is easy to define new types.

Humans like to use the *decimal number* system for representing numbers. Decimal numbers are *base* 10 means that for a number consisting of a sequence of digits separated by a *decimal point*, where each *digit* can have values $d \in \{0, 1, 2, \ldots, 9\}$, and the value, which each digit represents is proportional to its position. As an example 35.7 is a decimal number, whose value is $3 \cdot 10^1 + 5 \cdot 10^0 + 7 \cdot 10^{-1}$. In F# a decimal number is called a *floating point number* and in this text we use *Extended Backus-Naur Form (EBNF)* to describe the grammar of F#, the decimal number just described is given as,

· decimal number
· base
· decimal point
· digit
· floating point number
· Extended Backus-Naur Form
· EBNF

```
digit = "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9"
int = digit {digit}
float = int "." {digit}
```

---

[1]**We should start by giving examples of int, xint, float, char, string literals without literal types. Then then binding to identifiers incl. the it identdifier.**

Metatype	Type name	Description
Boolean	bool	Boolean values true or false
Integer	**int**	Integer values from -2,147,483,648 to 2,147,483,647
	byte	Integer values from 0 to 255
	sbyte	Integer values from -128 to 127
	int8	Synonymous with byte
	uint8	Synonymous with sbyte
	int16	Integer values from -32768 to 32767
	uint16	Integer values from 0 to 65535
	int32	Synonymous with int
	uint32	Integer values from 0 to 4,294,967,295
	int64	Integer values from -9,223,372,036,854,775,808 to 9,223,372,036,854,775,807
	uint64	Integer values from 0 to 18,446,744,073,709,551,615
	nativeint	A native pointer as a signed integer
	unativeint	A native pointer as an unsigned integer
Real	**float**	64-bit IEEE 754 floating point value from $-\infty$ to ∞
	double	Synonymous with float
	single	A 32-bit floating point type
	float32	Synonymous with single
	decimal	A floating point data type that has at least 28 significant digits
Character	**char**	Unicode character
	string	Unicode sequence of characters
None	**unit**	No value denoted
Object	**obj**	An object
Exception	**exn**	An exception

Table 5.1: List of basic types. The most commonly used types are highlighted in bold. For at description of integer see Appendix A.1, for floating point numbers see Appendix A.2, for ASCII and Unicode characters see Appendix B, for objects see Chapter 18, and for exceptions see Chapter 11.

meaning that a digit is either "0" or "1" or ... or "9", an `int` is 1 or more digits, and a `float` is 1 or more digits, a dot and 0 or more digits. There is no space between the digits and between digits and the dot. So `3`, `049` are examples of integers, `34.89 3.` are examples of floats, while `.5` is neither. Floating point numbers may alternatively be given using exponential notation, such as `3.5e-4`, which means the number $3.510^{-4} = 0.0035$, so to describe this in EBNF we write

```
digit = "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9"
int = digit {digit}
simpleFloat = int "." {digit}
expFloat = int ["." {digit}] ("e" | "E" ) ["+" | "-"] int
float = simpleFloat | expFloat
```

The basic unit of information in almost all computers is the binary digit or *bit* for short. A *binary* number consists of a sequence of binary digits separated by a decimal point, where each digit can have values $b \in \{0, 1\}$, and the base is 2. E.g., the binary number $101.01_2 = 1 \cdot 2^2 + 0 \cdot 2^1 + 1 \cdot 2^0 + 0 \cdot 2^{-1} + 1 \cdot 2^1 = 5.25$. Binary numbers are closely related to octal and hexadecimal numbers, where octals uses 8 as basis and can be written in binary using 3 bits, while hexadecimal numbers uses 16 as basis and can be written in binary using 4 bits. Octals and hexadecimals thus conviniently serve as shorthand for the much longer binary representation. F# has a syntax for wrting integers on binary, octal, decimal, and hexadecimal numbers as,

· bit

· binary

```
bDigit = "0" | "1"
oDigit  = bDigit | "2" | "3" | "4" | "5" | "6" | "7"
digit = oDigit | "8" | "9"
xDigit  =
  digit
  | "A" | "B" | "C" | "D" | "E" | "F"
  | "a" | "b" | "c" | "d" | "e" | "f"
int = digit {digit}
bitInt = "0" ("b" | "B") bDigit {bDigit}
octInt = "0" ("o" | "O") oDigit {oDigit}
hexInt = "0" ("x" | "X") xDigit {xDigit}
xint = bitInt | octInt | hexInt
```

For example `367` is an `int`, `0b101101111`, `0o557`, and `0x16f` are examples of an `xint` each representing the number 367, while `0b12` are `ff` neither an `int` nor an `xint`.

A character is a Unicode code point, see Appendix B.3 for a description of code points, and character literals enclosed in single quotation marks,[2]

```
escapeCodePoint =
  "\u" xDigit xDigit xDigit xDigit
  | "\U" xDigit xDigit xDigit xDigit xDigit xDigit xDigit xDigit
  | "\" digit digit digit
escapeChar =
  "\" ("b" | "n" | "r" | "t" | "\" | '"' | "'" | "a" | "f" | "v")
  | escapeCodePoint
char = "'" codePoint | escapeChar "'"
```

where `codePoint` is a UTF8 encoding of a char. The escape characters `escapeChar` are code points or escape sequence starting with \ as illustrated in Table 5.2, and the trigraph \DDD uses decimal specification for the first 256 unicode characters. The hexadecimal escape codes \uXXXX, \UXXXXXXXX allow for the full specification of any unicode character. Examples of a `char` are `'a'`, `'_'`, `'\n'`, and `'\065'`.

A string is a sequence of characters enclosed in double quotation marks,[3]

```
    string-expr = '"' { char | LF | SP }  '"'
```

---

[2]**Spec-4.0 p.28:** `char-char` **is missing option** `unicodegraph-long`
[3]**Spec-4.0 p. 28-29:** `simple-string-char` **is undefined,** `string-elem` **is unused.**

Character	Escape sequence	Description
BS	\b	Backspace
LF	\n	Newline
CF	\r	Carriage return
HT	\t	Horizontal tabulation
\	\\	Backslash
"	\"	Quotation mark
'	\'	Apostrophe
BEL	\a	Bell
FF	\f	Form feed
VT	\v	Vertical tabulation
	\uXXXX, \UXXXXXXXX, \DDD	Unicode character

Table 5.2: Escape characters. For the unicode characters 'X' are hexadecimal digits, while for tricode characters 'D' is a decimal character.

Examples are `"a"`, `"this is a string"`, and `"-&#\@"`. Newlines and following whitespaces are taken literally, but may be ignored by a preceding \character. Further examples of strings are,

```
> "abcde";;
val it : string = "abcde"
> "abc
-    de";;
val it : string = "abc
  de"
> "abc\
-    de";;
val it : string = "abcde"
> "abc\nde";;
val it : string = "abc
de"
```

Listing 5.3: fsharpi, Examples of string literals.

The response is shown in double quotation marks, which are not part of the string.
F# supports *literal types*, where the type of a literal is indicated as a prefix og suffix as shown in the   · literal type
Table 5.3. Examples are,

```
> 3;;
val it : int = 3
> 4u;;
val it : uint32 = 4u
> 5.6;;
val it : float = 5.6
> 7.9f;;
val it : float32 = 7.9000001f
> 'A';;
val it : char = 'A'
> 'B'B;;
val it : byte = 66uy
> "ABC";;
val it : string = "ABC"
```

Listing 5.4: fsharpi, Named and implied literals.

Strings literals may be *verbatim* by preceding the string with '@', meaning that the escape sequences   · verbatim
are not converted to their code point, e.g.,

```
> @"abc\nde";;
```

type	EBNF	Examples
int, int32	(int | xint) ["l"]	3
uint32	(int | xint) ("u"| "ul")	3u
byte, uint8	((int | xint) "uy") | (char "B")	3uy
byte[]	["@"] string "B"	"abc"B and "@http:\\\\"B
sbyte, int8	(int | xint) "y"	3y
int16	(int | xint) "s"	3s
uint16	(int | xint) "us"	3us
int64	(int | xint) "L"	3L
uint64	(int | xint) ("UL"| "uL")	3UL and 3uL
bignum*	int "I"	3I
nativeint	(int | xint) "n"	3n
unativeint	(int | xint) "un"	3un
float, double	float | (xint "LF")	3.0
single, float32	(float ("F"| "f")) | (xint "lf")	3.0f
decimal	(float | int) ("M"| "m")	3.0m and 3m
string	["@"] string	"abc" and @"http:\\\\"

Table 5.3: List of literal type. No spacing is allowed between the literal and the prefix or suffix. *bignum does not yet have an implementation for int ("Q"|"R"|"Z"|"N"|"G") in Mono.

```
val it : string = "abc\nde"
```
Listing 5.5: fsharpi, Examples of a string literal.

Verbatim literals containing double quotation marks are escaped with an extra double quotation mark, or the alternative tripple double quotation mark may be used, e.g.,

```
> @"This is a verbatim ""quote"".";;
val it : string = "This is a verbatim "quote"."
> """This is a verbatim "quote"."""";;
val it : string = "This is a verbatim "quote"."
```
Listing 5.6: fsharpi, Example of double quotation marks in verbatim string literals.

Many basic types are compatible and the type of a literal may be changed by *type casting*. E.g.,   · type casting

```
> float 3;;
val it : float = 3.0
```
Listing 5.7: fsharpi, Casting an integer to a floating point number.

which is a float, since the integer number 3 is casted to float resulting in a similar floating point value, in this case the float point number 3.0. As a technical detail, float is here a function rather than a type, which takes the argument 3 and returns the value 3.0. For more on functions see Section 7. Boolean values are often treated as the integer values 0 and 1, but no short-hand function names exists for their conversions. Instead use,

```
> System.Convert.ToBoolean 1;;
val it : bool = true
> System.Convert.ToBoolean 0;;
val it : bool = false
> System.Convert.ToInt32 true;;
val it : int = 1
> System.Convert.ToInt32 false;;
val it : int = 0
```
Listing 5.8: fsharpi, Casting booleans.

Here `System.Convert.ToBoolean` is the identifier of a function `ToBoolean`, which is a *member* of the *class* `Convert` that is included in the *namespace* `System`. Namespaces, classes, and members are all part of Structured programming to be discussed in Part IV.

Type casting is often a destructive operation, e.g., type casting a `float` to `int` removes the part after the decimal point without rounding,

```
> int 357.6;;
val it : int = 357
```

Listing 5.9: fsharpi, Fractional part is removed by downcasting.

Here we type casted to a lesser type, in the sense that integers is a subset of floating point numbers, which is called *downcasting*. The opposite is called *upcasting* is often non-destructive, as Listing 5.7 showed, where an integer was casted to a float while retaining its value. As a side note, *rounding* a number $y.x$, where y is the *whole part* and x is the *fractional part*, is the operation of mapping numbers in the interval $y.x \in [y.0, y.5)$ to y and $y.x \in [y.5, y+1)$ to $y+1$. This can be performed by downcasting as follows,

```
> int (357.6 + 0.5);;
val it : int = 358
```

Listing 5.10: fsharpi, Fractional part is removed by downcasting.

since if $y.x \in [y.0, y.5)$, then $y.x + 0.5 \in [y.5, y+1)$, from which downcasting removes the fractional part resulting in y. And if $y.x \in [y.5, y+1)$, then $y.x + 0.5 \in [y+1, y+1.5)$, from which downcasting removes the fractional part resulting in $y + 1$. Hence, the result is rounding.

If parentheses are omitted in Listing 5.10, then F# will interpret the expression as `(int 357.6) + 0.5`, which is erroneous, since addition of an integer with a float is undefined. This is an example of precedence, i.e., function evaluation takes precedence over addition meaning that it is performed before addition. Consider the arithmetic expression, whose result is bound to `a` by

```
> 3 + 4 * 5;;
val it : int = 23
```

Listing 5.11: fsharpi, A simple arithmetic expression.

Here, the addition and multiplication functions are shown in *infix notation* with the *operator* tokens `+` and `*`. To arrive at the resulting value 23, F# has to decide in which order to perform the calculation. There are 2 possible orders, `3 + (4 * 5)` or `(3 + 4) * 5`, which gives different results. For integer arithmetic, the correct order is of course to multiply before addition, and we say that multiplication takes *precedence* over addition. Every atomic operation that F# can perform is ordered in terms of its precedences, and for some common built-in operators shown in Table 5.4, the precedence is shown by the order they are given in the table. Associativity implies the order in which calculations are performed for operators of same precedence. For some operators and type combinations association matters little, e.g., multiplication associates to the left and exponentiation associates to the right, e.g., in[4]

```
> 3.0*4.0*5.0;;
val it : float = 60.0
> (3.0*4.0)*5.0;;
val it : float = 60.0
> 3.0*(4.0*5.0);;
val it : float = 60.0
> 4.0 ** 3.0 ** 2.0;;
val it : float = 262144.0
> (4.0 ** 3.0) ** 2.0;;
val it : float = 4096.0
```

---

[4]**Spec-4.0, Table 18.2.1 appears to be missing boolean 'and' and 'or' operations. Section 4.4 seems to be missing &&& and ||| bitwise operators.**

Operator	Associativity	Example	Description
`+op, -op, ~~~op`	Left	`-3`	Unary identity, negation, and bitwise negation operator
`f x`	Left	`f 3`	Function application
`op ** op`	Right	`3.0 ** 2.0`	Exponent
`op * op, op / op, op % op`	Left	`3.0 / 2.0`	Multiplication, division and remainder
`op + op, op - op`	Left	`3.0 + 2.0`	Addition and subtraction binary operators
`op ^^^ op`	Right	`0xAAuy ^^^ 0xFFuy`	bitwise exclucive or
`op < op, op <= op,` `op > op, op >= op,` `op = op, op <> op,` `op <<< op, op >>> op,` `op &&& op, op ||| op,`	Left	`3 > 5`	Comparison operators, bitwise shift, and bitwise 'and' and 'or'.
`&&`	Left	`true && true`	Boolean and
`||`	Left	`true || true`	Boolean or

Table 5.4: Some common operators, their precedence, and their associativity. Rows are ordered from highest to lowest precedences, such that `op * op` has higher precedence than `op + op`. Operators in the same row has same precedence.

```
> (3.0 ** 2.0);;
val it : float = 9.0
```

Listing 5.12: fsharpi, Precedences rules define implicite parantheses.

the expression for `a` is interpreted as `b` but gives the same results as `c` since association does not matter for multiplication of numbers, but the expression for `d` is interpreted as `f` which is quite different from `e`.

A less common notation is to define bindings for expressions using the *in* keyword, e.g.,   · `in`

```
let p = 2.0 in printfn "%A" (3.0 ** p)
```

```
9.0
```

Listing 5.13: numbersIn.fsx - The identifier `p` is only bound in the nested scope following the keyword `in`.

Here `p` is only bound in the *scope* of the expression following the `in` keyword, in this the `printfn`   · scope
statement, and `p` is unbound in lines that follows.

5.1 Booleans

Boolean arithmetic is the basis of almost all computers and particularly important for controlling program flow, which will be discussed in Chapter 9. Boolean values are one of 2 possible values, true or false, which is also sometimes written as 1 and 0. Two basic operations on boolean values are '*and*'   · and
often also written as multiplication, and '*or*' often written as addition, and '*not*' often written as a   · or
bar above the value. All possible combination of input on these values can be written on tabular   · not
form, known as a *truth table*, shown in Table 5.5. That is, the multiplication and addition are good   · truth table
mnemonics for remembering the result of the 'and' and 'or' operators. In F# the values `true` and
`false` are used, and the operators `&&` for 'and', `||` for 'or', and the function `not` for 'not', such that
the above table is reproduced by,

a	b	$a \cdot b$	$a + b$	$\bar{a}$
0	0	0	0	1
0	1	0	1	1
1	0	0	1	0
1	1	1	1	0

Table 5.5: Truth table for boolean 'and', 'or', and 'not' operators. Value 0 is false and 1 is true.

```
> let t = true
- let f = false
- printfn "a      b      a*b    a+b    not a"
- printfn "%A %A %A %A %A" f f (f && f) (f || f) (not f)
- printfn "%A %A  %A %A  %A" f t (f && t) (f || t) (not f)
- printfn "%A  %A %A %A  %A" t f (t && f) (t || f) (not t)
- printfn "%A  %A  %A  %A  %A" t t (t && t) (t || t) (not t);;
a      b      a*b    a+b    not a
false false false false true
false true  false true   true
true  false false true   false
true  true  true   true   false

val t : bool = true
val f : bool = false
val it : unit = ()
```

Listing 5.14: fsharpi, Boolean operators and truth tables.

Careful spacing in the format string of the `printfn` function was used to align columns. Next section will discuss more elegant formatting options.

5.2 Integers and Reals

The set of integers and reals are infinitely large, and since all computers have limited resources, it is not possible to represent these sets in their entirety. The various integer and floating point types listed in Table 5.1 are finite subset where the integer types have been reduced by limiting their ranges and the floating point types have been reduced by sampling the space of reals. An in-depth description of integer and floating point implementations can be found in Appendix A. The `int` and `float` are the most common types.

For integers the following arithmetic operators are defined:

`+op, -op:` These are unary plus and minus operators, and plus has no effect, but minus changes the sign, e.g.,

```
> let a = 5
- let b = -a;;

val a : int = 5
val b : int = -5
```

Listing 5.15: fsharpi, unary integer negation operator.

`op + op, op - op, op * op:` These are binary operators, where addition, subtraction and multiplication performs the usual operations,

```
> let a = 7 + 3
- let b = 7 - 3
- let c = 7 * 3;;
```

```
val a : int = 10
val b : int = 4
val c : int = 21
```

Listing 5.16: fsharpi, binary integer addition, subtraction, and multiplication operators.

op / op, op % op: These are binary operators, and division performs integer division, where the fractional part is discarded after division, and the \% is the remainder operator, which calculates the remainder after integer division,

```
> let a = 7 / 3
- let b = 7 % 3;;

val a : int = 2
val b : int = 1
```

Listing 5.17: fsharpi, binary integer division and remainder operators.

Together integer division and remainder is a lossless representation of the original number as,

```
> let x = 7
- let whole = x / 3
- let remainder = x % 3
- let y = whole * 3 + remainder;;

val x : int = 7
val whole : int = 2
val remainder : int = 1
val y : int = 7
```

Listing 5.18: fsharpi, binary division and remainder is a lossless representation of an integer.

And we see that x and y is bound to the same value.

Integer exponentiation is not defined as an operator, but this is available the built-in function pown, e.g.,

```
> pown 2 5;;
val it : int = 32
```

Listing 5.19: fsharpi, integer exponentiation function, and the irrelevant identifier.

which is equal to 2^5. Note that when no let statement is used in conjunction with an expression then F# automatically binds the result to the *it* identifier, i.e., the above is equal to · it

```
  > let it = pown 2 5;;

val it : int = 32
```

Listing 5.20: fsharpi, the equivalent to the irrelevant identifier.

Rumor has it, that the identifier it is an abbreviation for 'irrelevant'.

Performing arithmetic operations on int types requires extra care, since the result may cause *overflow*, · overflow
underflow, and even exceptions, e.g., the range of the integer type sbyte is $[-128 \dots 127]$, which causes · underflow
problems in the following example,

```
> let a = 100y
- let b = 30y
- let c = a+b;;

val a : sbyte = 100y
```

```
val b : sbyte = 30y
val c : sbyte = -126y
```

Listing 5.21: fsharpi, adding integers may cause overflow.

Here $100 + 30 = 130$, which is larger than the biggest `sbyte`, and the result is an overflow. Similarly, we get an underflow, when the arithmetic result falls below the smallest value storable in an `sbyte`,

```
> let a = -100y
- let b = -30y
- let c = a+b;;

val a : sbyte = -100y
val b : sbyte = -30y
val c : sbyte = 126y
```

Listing 5.22: fsharpi, subtracting integers may cause underflow

Notice that neither overflow nor underflow error gave rise to an error message, which is why such bugs are difficult to find. Dividing any non-zero number with 0 is infinite, which is also outside the domain of any of the integer types, but in this case, F# casts an *exception*,   · exception

```
> 3/0;;
System.DivideByZeroException: Attempted to divide by zero.
  at <StartupCode$FSI_0007>.$FSI_0007.main@ () <0x6b78180 + 0x0000e> in <filename unknown>:0
  at (wrapper managed-to-native) System.Reflection.MonoMethod:InternalInvoke (System.Reflection.
  at System.Reflection.MonoMethod.Invoke (System.Object obj, BindingFlags invokeAttr, System.Ref
Stopped due to error
```

Listing 5.23: fsharpi, integer division by zero causes an exception run-time error.

The output looks daunting at first sight, but the first and last line of the error message are the most important parts, which tells us what exception was cast and why the program stopped. The middle are technical details concerning which part of the program caused this, and can be ignored for the time being. Exceptions are a type of *run-time error*, and are treated in Chapter 11   · run-time error
Integers can also be written in binary, octal, or hexadecimal format using the prefixes `0b`, `0o`, and `0x`, e.g.,

```
> let a = 0b1011
- let b = 0o13
- let c = 0xb;;

val a : int = 11
val b : int = 11
val c : int = 11
```

Listing 5.24: fsharpi, integer types may be specified as binary, octal, and hexadecimal numbers.

For a description of binary representations see Appendix A.1. The overflow error in Listing 5.21 can be understood in terms of the binary representation of integers: In binary, $130 = 10000010_2$, and this binary pattern is interpreted differently as `byte` and `sbyte`,

```
> let a = 0b10000010uy
- let b = 0b10000010y;;

val a : byte = 130uy
val b : sbyte = -126y
```

Listing 5.25: fsharpi, the left most bit is interpreted differently for signed and unsigned integers, which gives rise to potential overflow errors.

That is, for signed bytes, the left-most bit is used to represent the sign, and since the addition of $100 = 01100100_2$ and $30 = 00011110_b$ is $130 = 10000010_2$ causes the left-most bit to be used, then this is wrongly interpreted as a negative number, when stored in an `sbyte`.

For binary arithmatic on integers, the following operators are available:

op $<<<$ n: Bitwise left shift, shifts any integer bit pattern n positions to the left insert 0's to right.

op $>>>$ n: Bitwise left right, shifts any integer bit pattern n positions to the right insert 0's to left.

op1 &&& op2: Bitwise 'and', returns the result of taking the boolean 'and' operator position-wise.

op ||| op: Bitwise 'or', as 'and' but using the boolean 'or' operator

op1 ~~~ op1: Bitwise xor, which is returns the result of the boolean 'xor' operator defined by,

a	b	a xor b
0	0	0
0	1	1
1	0	1
0	1	0

position-wise.

Unfortunately, there are no built-ind functions outputting integers on binary form, so to understand the output of the following program,

```
> let a = 0b11000011uy
- let b = a <<< 1
- let c = a >>> 1
- let d = ~~~a
- let e = a ^^^0b11111111uy;;

val a : byte = 195uy
val b : byte = 134uy
val c : byte = 97uy
val d : byte = 60uy
val e : byte = 60uy
```

Listing 5.26: fsharpi, the left most bit is interpreted differently for signed and unsigned integers, which gives rise to potential overflow errors.

we must consider the 8-bit binary form of the unsigned integers: $195 = 11000011_2$, $134 = 10000110_2$, $97 = 01100001_2$, and $60 = 00111100_2$, which agrees with the definitions. [5]

For floating point numbers the following arithmetic operators are defined:

+op, -op: These are unary plus and minus operators, and plus has no effect, but minus changes the sign, e.g.,

```
> let a = 5.0
- let b = -a;;

val a : float = 5.0
val b : float = -5.0
```

Listing 5.27: fsharpi, unary floating point negation operator.

op + op, op - op, op * op, op / op: These are binary operators, where addition, subtraction, multiplication, and division performs the usual operations,

---

[5]mention somewhere that comparison operators will be treated later.

```
> let a = 7.0 + 3.0
- let b = 7.0 - 3.0
- let c = 7.0 * 3.0
- let d = 7.0 / 3.0;;

val a : float = 10.0
val b : float = 4.0
val c : float = 21.0
val d : float = 2.333333333
```

Listing 5.28: fsharpi, binary floating point addition, subtraction, multiplication, and division operators.

op % op: The binary remainder operator, and division performs integer division, where the fractional part is discarded after division, and the \% is the remainder operator, which calculates the remainder after integer division,

```
> let a = 7.0 / 3.0
- let b = 7.0 % 3.0;;

val a : int = 2.0
val b : int = 1.0
```

Listing 5.29: fsharpi, binary floating point division and remainder operators.

The remainder for floating point numbers can be fractional, but division, rounding, and remainder is still a lossless representation of the original number as,

```
> let x = 7.0
- let division = x / 3.2
- let whole = float (int (division + 0.5))
- let remainder = x % 3.2
- let y = whole * 3.2 + remainder;;

val x : float = 7.0
val division : float = 2.1875
val whole : float = 2.0
val remainder : float = 0.6
val y : float = 7.0
```

Listing 5.30: fsharpi, floating point division, truncation, and remainder is a lossless representation of a number.

And we see that x and y is bound to the same value.

op ** op: In spite of an unusual notation, the binary exponentiation operator performs the usual calculation,

```
> let a = 2.0 ** 5.0;;

val a : float = 32.0
```

Listing 5.31: fsharpi, binary floating point exponentiation.

which is equal to 2^5.

Arithmetic using `float` will not cause over- and underflow problems, since the IEEE 754 standard includes the special numbers $\pm\infty$ and NaN. E.g.,

```
> let a = 1.0/0.0
- let b = 0.0/0.0;;

val a : float = infinity
val b : float = nan
```

Listing 5.32: fsharpi, floating point numbers include infinity and Not-a-Number

However, the `float` type has limite precision, since there is only a finite number of numbers that can be stored in a float. E.g.,

```
> let a = 357.8
- let b = a+0.1
- let c = b+0.1
- let d = c - 358.0;;

val a : float = 357.8
val b : float = 357.9
val c : float = 358.0
val d : float = 5.684341886e-14
```

Listing 5.33: fsharpi, floating point arithmatic has finite precision.

Hence, although `c` appears to be correctly calculated, by the subtraction we see, that the value bound in `c` is not exactly the same as `358.0`, and the reason is that the neither `357.8` nor `0.1` are exactly representable as a `float`, which is why the repeated addition accumulates a small representation error. F# allows for assigning *unit of measure* to the following types,   · unit of measure

sbyte, int, int16, int32, int64, single, float32, float, and decimal.

by using the syntax,

```
"[<Measure>] type" unit-name [ "=" measure ]
```

and then use `"<"` unit-name `">"` as suffix for literals. In Figure **??**
E.g., defining unit of measure 'm' and 's', then we can make calculations like,

```
> [<Measure>] type m
- [<Measure>] type s
- let a = 3<m/s^2>
- let b = a * 10<s>
- let c = 4 * b;;

[<Measure>]
type m
[<Measure>]
type s
val a : int<m/s ^ 2> = 3
val b : int<m/s> = 30
val c : int<m/s> = 120
```

Listing 5.34: fsharpi, floating point and integer numbers may be assigned unit of measures.

However, if we mixup unit of measures under addition, then we get an error,

```
> [<Measure>] type m
- [<Measure>] type s
- let a = 1<m>
- let b = 1<s>
- let c = a + b;;
```

```
   let c = a + b;;
   ------------^

/Users/sporring/repositories/fsharpNotes/stdin(63,13): error FS0001: The unit of measure 's' doe
```

Listing 5.35: fsharpi, unit of measures adds an extra layer of types for syntax checking at compile time.

Unit of measures allow for *, /, and ^[6] for multiplication, division and exponentiation. Values with units can be casted to *unit-less* values by casting, and back again by multiplication as,   · unit-less

```
> [<Measure>] type m
- let a = 2<m>
- let b = int a
- let c = b * 1<m>;;

[<Measure>]
type m
val a : int<m> = 2
val b : int = 2
val c : int<m> = 2
```

Listing 5.36: fsharpi, type casting unit of measures.

Compound symbols can be declared as,

```
> [<Measure>] type s
- [<Measure>] type m
- [<Measure>] type kg
- [<Measure>] type N = kg * m / s^2;;

[<Measure>]
type s
[<Measure>]
type m
[<Measure>]
type kg
[<Measure>]
type N = kg m/s ^ 2
```

Listing 5.37: fsharpi, aggregated unit of measures.

For fans of the metric system there is the International System of Units, and these are built-in in `Microsoft.FSharp.Data.UnitSystems.SI.UnitSymbols` and give in Table 5.6. Hence, using the predefined unit of seconds, we may write,

```
> let a = 10.0<Microsoft.FSharp.Data.UnitSystems.SI.UnitSymbols.s>;;

val a : float<Data.UnitSystems.SI.UnitSymbols.s> = 10.0
```

Listing 5.38: fsharpi, SI unit of measures are built-in.

To make the use of these predefined symbols easier, we can import them into the present scope by the *open* keyword,   · open

```
> open Microsoft.FSharp.Data.UnitSystems.SI.UnitSymbols;;
> let a = 10.0<s>;;

val a : float<s> = 10.0
```

Listing 5.39: fsharpi, simpler syntax by importing, but beware of namespace polution.

---

[6]**Spec-4.0: this notation is inconsistent with ** for float exponentiation.**

Unit	Description
A	Ampere, unit of electric current.
Bq	Becquerel, unit of radioactivity.
C	Coulomb, unit of electric charge, amount of electricity.
cd	Candela, unit of luminous intensity.
F	Farad, unit of capacitance.
Gy	Gray, unit of an absorbed dose of radiation.
H	Henry, unit of inductance.
Hz	Hertz, unit of frequency.
J	Joule, unit of energy, work, amount of heat.
K	Kelvin, unit of thermodynamic (absolute) temperature.
kat	Katal, unit of catalytic activity.
kg	Kilogram, unit of mass.
lm	Lumen, unit of luminous flux.
lx	Lux, unit of illuminance.
m	Metre, unit of length.
mol	Mole, unit of an amount of a substance.
N	Newton, unit of force.
ohm	Unitnames.o SI unit of electric resistance.
Pa	Pascal, unit of pressure, stress.
s	Second, unit of time.
S	Siemens, unit of electric conductance.
Sv	Sievert, unit of dose equivalent.
T	Tesla, unit of magnetic flux density.
V	Volt, unit of electric potential difference, electromotive force.
W	Watt, unit of power, radiant flux.
Wb	Weber, unit of magnetic flux.

Table 5.6: International System of Units.

The `open` keyword should be used with care, since now all the bindings in `Microsoft.FSharp.Data.UnitSystems.SI.UnitSymbols`
have been imported into the present scope, and since we most likely do not know, which bindings have
been used by the programmers of `Microsoft.FSharp.Data.UnitSystems.SI.UnitSymbols`, we do
not know which identifiers to avoid, when using `let` statements. We have obtained, what is known as
namespace pollution. Read more about namespaces in Part IV.   · namespace
Using unit of measures is advisable for calculations involving real-world values, since some semantical   pollution
errors of arithmetic expressions may be discovered by checking the resulting unit of measure.
[7]

5.3   Chars and Strings

***

Character arithmatic is most often done by in integer space. A typical example is conversion of case,
e.g., to convert the lowercase character 'z' to uppercase, we use the *ASCIIbetical order* and add the   · ASCIIbetical
difference between any Basic Latin Block letters in upper- and lowercase as `integers` and cast back   order
to `char`, e.g.,

```
> char (int 'z' - int 'a' + int 'A');;
val it : char = 'Z'
```

Listing 5.40: fsharpi, converting case by casting and integer arithmatic.

*****

Operations on `string` is quite rich. The most simple is concatenation using `+` token, e.g.,

```
> let a = "hello"
- let b = "world"
- let c = a + " " + b;;

val a : string = "hello"
val b : string = "world"
val c : string = "hello world"
```

Listing 5.41: fsharpi, example of string concatenation.

Characters and strings cannot be concatenated, which is why the above example used the string of a
space `" "` instead of the space character `' '`. The characters of a string may be indexed as,

```
> let a = "abcdefg"
- let b = a.[0]
- let c = a.[3]
- ;;

val a : string = "abcdefg"
val b : char = 'a'
val c : char = 'd'
```

Listing 5.42: fsharpi, example of string indexing.

The *dot notation* is an example of Structured programming, where technically `a` is an immutable *object*   · dot notation
of *class* `string`, and `[]` is an object *method*. For more on object, classes, and methods see Chapter 18.   · object
Notice, that the first character has index 0, and to get the last character in a string, we use the string's   · class
lenght property as,   · method

```
> let a = "abcdefg"
- let l = a.Length
- let first = a.[0]
- let last = a.[l-1];;
```

---

[7]**add comparsion operators!**

```
val a : string = "abcdefg"
val l : int = 7
val first : char = 'a'
val last : char = 'g'
```

Listing 5.43: fsharpi, string length attribute and string indexing.

Notice, since index counting starts at 0, and the string length is 7, then the index of the last character is 6. An alternative notation for indexing is to use the property `Char`, and in the example `a.[3]` is the same as `a.Char 3`. The is a long list of built-in functions in `System.String` for working with strings, some of which will be discussed in Chapter 15.1.

Chapter 6

Identifiers, functions, and variables

An identifier is bound to an expression by the syntax,

```
"let" [ "mutable" ] ident [":" type] "=" expr ["in" expr]
```

That is, the *let* keyword indicates that the following is a binding of an identifier with an expression, and that the type may be specified with the *:* token. An identifier must start with a letter, but can be followed by zero or more of letters, digits, and a range of special characters. For characters in the Basic Latin Block, i.e., the first 128 code points alias ASCII characters, an ident is,

· let
· :

```
digit = "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9"
letter = "A" | "B" | ... |  "Z" | "a" | "b" | ... | "z"
special-char = "_"
ident = (letter | "_") {letter | digit | special-char}
```

Thus, examples of identifiers are a, theCharacter9, Next_Word, _tok. The for the full definition, letter = Lu | Ll | Lt | Lm | Lo | Nl and special-char = Pc | Mn | Mc | Cf, which referes to the Unicode general categories described in Appendix B.3, and there are currently 19.345 possible Unicode code points in the letter category and 2.245 possible Unicode code points in the special-char category. An identifier must not be a keyword or a reserved-keyword, shown in Figure 6.1 and 6.2. The binding may be mutable, which will be discussed in Section 6.2, and the binding may only be for the last expression as indicated by the *in* keyword. The simplest example of an expression is a *literal*, i.e., a constant such as the number 3.

· in
· literal

6.1 Values (Constant bindings)

When specifying the type, the type and the literal form must match, i.e., mixing types and literals gives an error,

```
> let a : float = 3;;

let a : float = 3;;
----------------^
```

abstract, and, as, assert, base, begin, class, default, delegate, do, done, downcast, downto, elif, else, end, exception, extern, false, finally, for, fun, function, global, if, in, inherit, inline, interface, internal, lazy, let, match, member, module, mutable, namespace, new, null, of, open, or, override, private, public, rec, return, sig, static, struct, then, to, true, try, type, upcast, use, val, void, when, while, with, and yield.

Figure 6.1: List of keywords in F#.

atomic, break, checked, component, const, constraint, constructor, continue, eager, fixed, fori, functor, include, measure, method, mixin, object, parallel, params, process, protected, pure, recursive, sealed, tailcall, trait, virtual, and volatile.

Figure 6.2: List of reserved keywords for possible future use in F#.

```
/Users/sporring/repositories/fsharpNotes/stdin(50,17): error FS0001: This expression was expecte
    float
but here has type
    int
```

Listing 6.1: fsharpi, binding error due to type mismatch.

since the left-hand-side is an identifier of type float, while the right-hand-side is a literal of type integer.

6.2 Variables (Mutable bindings)

The mutable in let bindings means that the identifier may be rebound to a new value using the following syntax,

```
ident "<-" expr
```

Mutable data is synonymous with the term *variable*. A variable is an area in the computers working memory associated with an identifier and a type, and this area may be read from and written to during program execution. For example,

· Mutable data
· variable

```
let mutable x = 5
printfn "%d" x
x <- -3
printfn "%d" x
```

```
5
-3
```

Listing 6.2: mutableAssignReassingShort.fsx - A variable is defined and later reassigned a new value.

Here a area in memory was denoted x, initially assigned the integer value 5, hence the type was inferred to be int. Later, this value of x was replaced with another integer using the <- token. The <- token is used to distinguish the assignment from the comparison operator, i.e., if we by mistake had written,

· <-

```
> let mutable a = 0
- a = 3;;

val mutable a : int = 0
val it : bool = false
```

Listing 6.3: fsharpi, example of changing the content of a variable.

then we instead would have obtained the default assignment of the result of the comparision of the content of a with the integer 3, which is false. However, it's important to note, that when the variable is initially defined, then the '|=|' operator must be used, while later reassignments must use the |<-| operator.
Assignment type mismatches will result in an error,

```
let mutable x = 5
printfn "%d" x
x <- -3.0
printfn "%d" x
```

```
/Users/sporring/repositories/fsharpNotes/src/mutableAssignReassingTypeError.fsx(3,6): error FS00
     int
but here has type
     float
```

Listing 6.4: mutableAssignReassingTypeError.fsx - Assignmetn type mismatching causes a compile time error.

I.e., once the type of an identifier has been declared or infered, then it cannot be changed.
A typical variable is a counter of type integer, and a typical use of counters is to increment them, i.e., erasing a new value to be one more that its previous value. For example,

```
let mutable x = 5 // Declare a variable x and assign the value 5 to it
printfn "%d" x
x <- x + 1 // Assign a new value -3 to x
printfn "%d" x
```

```
5
6
```

Listing 6.5: mutableAssignIncrement.fsx - Variable increment is a common use of variables.

which is an example we will return to many times later in this text.

[1]

[2]

[2]Somewhere I should possibly talk about Lightweight Syntax, Spec-4.0 Chapter 15.1

Chapter 7

Functions and procedures (function bindings)

Function definition follows the same syntax as literal binding,

```
"let" ["rec"] ident valIdent {valIdent} [":" type] "=" expr ["in" expr]
valident = ident | "(" ident ":" type ")"
```

or specify the type of the function at point of definition using the notation,

```
"let" name argWType { argWType } [ ":" type ] "=" expr
argWType = arg | "(" arg ":" type ")"
```

where not all types need to be declared, just sufficent for F# to be able to infer the types for the full statement. In the example, one sufficent specification is,

```
> let sum (x : float) (y : float) = x + y;;

val sum : x:float -> y:float -> float

> let c = sum 357.6 863.4;;

val c : float = 1221.0
```

Listing 7.1: fsharpi

but alternatively we could have specified the type of the result,

```
let sum x y : float = x + y
```

or even just one of the arguments,

```
let sum (x : float) y = x + y
```

In both cases, since the + *operator* is only defined for *operands* of the same type, then when the type of either the result, any or both operands are declared, then the type of the remaining follows directly. A function that elegantly implements the incrementation operation may be constructed as,

· operator

· operand

```
let incr =
  let mutable counter = 0
  fun () ->
    counter <- counter + 1
    counter
printfn "%d" (incr ())
printfn "%d" (incr ())
printfn "%d" (incr ())
```

```
1
2
3
```

Listing 7.2: mutableAssignIncrementEncapsulation.fsx -

[1] Here the output of `incr` is an anonymous function, that takes no argument, increments the variable of `incr` and returns the new value of the counter. This construction is called *encapsulation*, since the · encapsulation variable `counter` is hidden by the function `incr` from the user, i.e., the user need not be concerned with how the increment operator is implemented and the variable name used by `incr` does not clutter the scope where it is used.

Variables cannot be returned from functions, that is,

```
let g () =
  let x = 0
  x
printfn "%d" (g ())
```

```
0
```

Listing 7.3: mutableAssignReturnValue.fsx -

declares a function that has no arguments and returns the value 0, while the same for a variable is illegal,

```
let g () =
  let mutual x = 0
  x
printfn "%d" (g ())
```

```
/Users/sporring/repositories/fsharpNotes/src/mutableAssignReturnVariable.fsx(3,3): error FS0039:
```

Listing 7.4: mutableAssignReturnVariable.fsx -

There is a workaround for this by using *reference cells* by the build-in function `ref` and operators |!| · reference cells and |:=|,

```
let g () =
  let x = ref 0
  x
let y = g ()
printfn "%d" !y
y := 3
printfn "%d" !y
```

```
0
3
```

Listing 7.5: mutableAssignReturnRefCell.fsx -

That is, the `ref` function creates a reference variable, the '|!|' and the '|:=|' operators reads and writes its value. Reference cells are in some language called pointers, and their use is strongly discouraged, since they may cause *side-effects*, which is the effect that one function changes the state of another, · side-effects such as the following example demonstrates,

---

[1]**Explain why this works!**

```
let updateFactor factor =
  factor := 2

let multiplyWithFactor x =
  let a = ref 1
  updateFactor a
  !a * x

printfn "%d" (multiplyWithFactor 3)
```

```
6
```

Listing 7.6: mutableAssignReturnSideEffect.fsx -

In the example, the function `updateFactor` changes a variable in the scope of `multiplyWithFactor`, which is prone to errors, since the style of programming does not follow the usual assignment syntax. Better style of programming is,

```
let updateFactor () =
  2

let multiplyWithFactor x =
  let a = ref 1
  a := updateFactor ()
  !a * x

printfn "%d" (multiplyWithFactor 3)
```

```
6
```

Listing 7.7: mutableAssignReturnWithoutSideEffect.fsx -

Here there can be no doubt in `multiplyWithFactor` that the value of 'a' is changing. Side-effects do have their use, but should in general be avoided at almost all costs, and in general it is advised to refrain from using ref cells.
A function is a mapping between an input and output domain. F# is a functional first programming language, and offers a number of alternative methods for specifying parameters. A simple example is,

```
let mul (x, y) = x*y
let z = mul (3, 5)
printfn "%d" z
```

```
15
```

Listing 7.8: functionDeclarationMul.fsx -

which declares a function of a tuple and returns their multiplication. The types are inferred from its first use in the second line, i.e., `mul` is `val mul : x:int * y:int -> int`. An argument may be of generic type for input, which need not be inferred without sacrificing type safety, e.g.,

```
let second (x, y) = y
let a = second (3, 5)
printfn "%A" a
let b = second ("horse", 5.0)
printfn "%A" b
```

```
5
5.0
```

Listing 7.9: functionDeclarationGeneric.fsx -

Here the function `second` does not use the first element in the tuple, `x`, and the type of the second element, `y`, can safely be anything.

Functions may be anonymously declared using the `fun` keyword,

```
let first = fun (x, y) -> x
printfn "%d" (first (5, 3))
```

```
5
```

Listing 7.10: functionDeclarationAnonymous.fsx -

Anonymous functions are often used as arguments to other functions, e.g.,

```
let apply (f, x, y)  = f (x, y)
let z = apply ((fun (a, b) -> a * b), 3, 6)
printfn "%d" z
```

```
18
```

Listing 7.11: functionDeclarationAnonymousAdvanced.fsx -

This is a powerfull concept, but can make programs hard to read, and overly use is not recommended. Functions may be declared using pattern matching, which is a flexible method for declaring output depending on conditions on the input value. The most common pattern matching method is by use of the `match with` syntax,

```
let rec factorial n =
  match n with
  | 0 -> 1
  | 1 -> 1
  | _ -> n * (factorial (n - 1))

printfn "%d" (factorial 5)
```

```
120
```

Listing 7.12: functionDeclarationMatchWith.fsx -

A short-hand only for functions of 1 parameter is the `function` syntax,

```
let rec factorial = function
  | 0 -> 1
  | 1 -> 1
  | n -> n * (factorial (n - 1))

printfn "%d" (factorial 5)
```

```
120
```

Listing 7.13: functionDeclarationFunction.fsx -

Note that the name given in the match, here `n`, is not used in the first line, and is arbitrary at the line of pattern matchin, and may even be different on each line. For these reasons is this syntax discouraged. Functions may be declared from other functions

```
let mul (x, y) = x*y
let double y = mul (2.0, y)
printfn "%g" (mul (5.0, 3.0))
printfn "%g" (double 3.0)
```

```
15
6
```

Listing 7.14: functionDeclarationTupleCurrying.fsx -

For functions of more than 1 argument, there exists a short notation, which is called *currying* in tribute of Haskell Curry,

· currying

```
let mul x y = x*y
let double = mul 2.0
printfn "%g" (mul 5.0 3.0)
printfn "%g" (double 3.0)
```

```
15
6
```

Listing 7.15: functionDeclarationCurrying.fsx -

Here `mul 2.0` is a partial specification of the function `mul x y`, where the first argument is fixed, and hence, `double` is a function of 1 argument being the second argument of `mul`. Currying is often used in functional programming, but generally currying should be used carefully, since currying may seriously reduce readability of code.

7.1   Procedures

A *procedure* is a generalisation of the concept of functions, and in contrast to functions procedures need not return values. An example, we've already seen is the `printfn`, which is used to print text on the console, but does not return a value. Coincidentally, since the console is a state, printing to it is a side-effect. Above we examined

· procedure

```
let updateFactor factor =
  factor := 2
```

which also does not have a return value. Procedural thinking is useful for encapsulation, but is prone to side-effects and should be minimized by being replaced by functional thinking.
[2]

---

[2]**Maybe explain the printf function, Spec-4.0 Section 6.3.16 'printf' Formats, but also max and min comparison functions and math functions Section 18.2.2 and 18.2.4?**

Chapter 8

Comments

Chapter 9

Controlling program flow

9.0.1 Blocks

[1]

9.0.2 Conditional expressions

```
"if" expr "then" expr
[{"elif" expr "then" expr}
"else" expr]
```

A basic flow control mechanism used both for functional and imperative programming is the `if-then-else` construction, e.g.,

```
let printOnlyPostiveValues x =
  if x > 0 then
    printfn "%d" x
printOnlyPostiveValues 3
printOnlyPostiveValues -3
```

```
3
```

Listing 9.1: flowIfThen.fsx -

I.e., if and only if the value of the argument is postive, then it will be printed on screen. More common is to include the `else`

```
let abs x =
  if x < 0 then
    -x
  else
    x
printfn "%d" (abs 3)
printfn "%d" (abs -3)
```

```
3
3
```

Listing 9.2: flowIfThenElse.fsx -

A common construction is a nested list of `if-then-else`,

---

[1]**begin-end**

```
let digitToString x =
  if x < 1 then
    '0'
  else
    if x < 2 then
      '1'
    else
      '2'

printfn "%c" (digitToString 1)
printfn "%c" (digitToString 3)
printfn "%c" (digitToString -3)
```

```
1
2
0
```

Listing 9.3: flowIfThenElseNested.fsx -

where the integers 0–2 are converted to characters, and integers outside this domain is converted to the nearest equivalent number. This construction is so common that a short-hand notation exists, and we may equivalently have written,

```
let digitToString x =
  if x < 1 then
    '0'
  elif x < 2 then
    '1'
  else
    '2'

printfn "%c" (digitToString 1)
printfn "%c" (digitToString 3)
printfn "%c" (digitToString -3)
```

```
1
2
0
```

Listing 9.4: flowIfThenElseNestedShort.fsx -

9.0.3   For and while loops

A major difference between functional and imperative programming is how loops are expressed. Consider the problem of printing the numbers 1 to 5 on the console with a `while` loop can be done as follows,

```
let mutable i = 1
while i <= 5 do
  printf "%d " i
  i <- i + 1
printf "\n"
```

```
1 2 3 4 5
```

Listing 9.5: flowWhile.fsx -

where the same result by recursion as

```
let rec prt a b =
  if a <= b then
    printf "%d " a
    prt (a + 1) b
  else
    printf "\n"
prt 1 5
```

```
1 2 3 4 5
```

Listing 9.6: flowWhileRecursion.fsx -

The counting example is so often used that a special notation is available, the `for` loop, where the above could be implemented as

```
for i = 1 to 5 do
  printf "%d " i
printf "\n"
```

```
1 2 3 4 5
```

Listing 9.7: flowFor.fsx -

Note that `i` is a value and not a variable here. For a more complicated example, consider the problem of calculating average grades from a list of courses and grades. Using the above construction, this could be performed as,

```
let courseGrades =
    ["Introduction to programming", 95;
     "Linear algebra", 80;
     "User Interaction", 85;]

let mutable sum = 0;
let mutable n = 0;
for i = 0 to (List.length courseGrades) - 1 do
  let (title, grade) = courseGrades.[i]
  printfn "Course: %s, Grade: %d" title grade
  sum <- sum + grade;
  n <- n + 1;
let avg =  (float sum) / (float n)
printfn "Average grade: %g" avg
```

```
Course: Introduction to programming , Grade: 95
Course: Linear algebra , Grade: 80
Course: User Interaction , Grade: 85
Average grade: 86.6667
```

Listing 9.8: flowForListsIndex.fsx -

However, an elegant alternative is available as

```
let courseGrades =
    ["Introduction to programming", 95;
     "Linear algebra", 80;
     "User Interaction", 85;]

let mutable sum = 0;
let mutable n = 0;
for (title, grade) in courseGrades do
```

```
  printfn "Course: %s, Grade: %d" title grade
  sum <- sum + grade;
  n <- n + 1;
let avg =  (float sum) / (float n)
printfn "Average grade: %g" avg
```

```
Course: Introduction to programming , Grade: 95
Course: Linear algebra , Grade: 80
Course: User Interaction , Grade: 85
Average grade: 86.6667
```

Listing 9.9: flowForLists.fsx -

This to be preferred, since we completely can ignore list boundary conditions and hence avoid out of range indexing. For comparison see a recursive implementation of the same,

```
let courseGrades =
    ["Introduction to programming", 95;
    "Linear algebra", 80;
    "User Interaction", 85;]

let rec printAndSum lst =
  match lst with
    | (title, grade)::rest ->
        printfn "Course: %s, Grade: %d" title grade
        let (sum, n) = printAndSum rest
        (sum + grade, n + 1)
    | _ -> (0, 0)
let (sum, n) = printAndSum courseGrades
let avg = (float sum) / (float n)
printfn "Average grade: %g" avg
```

```
Course: Introduction to programming , Grade: 95
Course: Linear algebra , Grade: 80
Course: User Interaction , Grade: 85
Average grade: 86.6667
```

Listing 9.10: flowForListsRecursive.fsx -

Note how this implementation avoids the use of variables in contrast to the previous examples.

Chapter 10

Tuples, Lists, Arrays, and Sequences

F# is tuned to work with lists.

10.1 Tuples

[1]

10.2 Lists

10.3 Arrays

10.3.1 1 dimensional arrays

Roughly speaking, arrays are mutable lists, and may be created and indexed in the same manner, e.g.,

```
let A = [| 1; 2; 3; 4; 5 |]
let B = [| 1 .. 5 |]
let C = [| for a in 1 ..5 do yield a |]

let printArray (a : int array) =
  for i = 0 to a.Length - 1 do
    printf "%d " a.[i]
  printf "\n"

printArray A
printArray B
printArray C
```

```
1 2 3 4 5
1 2 3 4 5
1 2 3 4 5
```

Listing 10.1: arrayCreation.fsx -

Notice that as for lists, arrays are indexed starting with 0, and that in this particular case it was necessary to specify the type of the argument for `printArray` as an array of integers with the `array` keyword. The `array` keyword is synonymous with '[]'. Arrays do not support pattern matching, cannot be resized, but are mutable,

---

[1]**remember fst and snd Spec-4.0 Section 18.2.7**

```
let A = [| 1; 2; 3; 4; 5 |]

let printArray (a : int array) =
  for i = 0 to a.Length - 1 do
    printf "%d " a.[i]
  printf "\n"

let square (a : int array) =
  for i = 0 to a.Length - 1 do
    a.[i] <- a.[i] * a.[i]

printArray A
square A
printArray A
```

```
1 2 3 4 5
1 4 9 16 25
```

Listing 10.2: arrayReassign.fsx -

Notice that in spite the missing `mutable` keyword, the function `square` still had the side-effect of squaring alle entries in `A`. Arrays support *slicing*, that is, indexing an array with a range results in a copy of array with values corresponding to the range, e.g.,

· slicing

```
let A = [| 1; 2; 3; 4; 5 |]
let B = A.[1..3]
let C = A.[..2]
let D = A.[3..]
let E = A.[*]

let printArray (a : int array) =
  for i = 0 to a.Length - 1 do
    printf "%d " a.[i]
  printf "\n"

printArray A
printArray B
printArray C
printArray D
printArray E
```

```
1 2 3 4 5
2 3 4
1 2 3
4 5
1 2 3 4 5
```

Listing 10.3: arraySlicing.fsx -

As illustrated, the missing start or end index implies from the first or to the last element.
There are quite a number of built-in procedures for all arrays some of which we summarize in Table 10.1.
Thus, the `arrayReassign.fsx` program can be written using arrays as,

```
let A = [| 1 .. 5 |]

let printArray (a : int array) =
  Array.iter (fun x -> printf "%d " x) a
  printf "\n"
```

append	Creates an array that contains the elements of one array followed by the elements of another array.
average	Returns the average of the elements in an array.
blit	Reads a range of elements from one array and writes them into another.
choose	Applies a supplied function to each element of an array. Returns an array that contains the results x for each element for which the function returns Some(x).
collect	Applies the supplied function to each element of an array, concatenates the results, and returns the combined array.
concat	Creates an array that contains the elements of each of the supplied sequence of arrays.
copy	Creates an array that contains the elements of the supplied array.
create	Creates an array whose elements are all initially the supplied value.
empty	Returns an empty array of the given type.
exists	Tests whether any element of an array satisfies the supplied predicate.
fill	Fills a range of elements of an array with the supplied value.
filter	Returns a collection that contains only the elements of the supplied array for which the supplied condition returns true.
find	Returns the first element for which the supplied function returns true. Raises System.Collections.Generic.KeyNotFoundException if no such element exists.
findIndex	Returns the index of the first element in an array that satisfies the supplied condition. Raises System.Collections.Generic.KeyNotFoundException if none of the elements satisfy the condition.
fold	Applies a function to each element of an array, threading an accumulator argument through the computation. If the input function is f and the array elements are i0...iN, this function computes f (...(f s i0)...) iN.
foldBack	Applies a function to each element of an array, threading an accumulator argument through the computation. If the input function is f and the array elements are i0...iN, this function computes f i0 (...(f iN s)).
forall	Tests whether all elements of an array satisfy the supplied condition.
isEmpty	Tests whether an array has any elements.
iter	Applies the supplied function to each element of an array.
init	. . .
length	Returns the length of an array. The System.Array.Length property does the same thing.
map	Creates an array whose elements are the results of applying the supplied function to each of the elements of a supplied array.
mapi	
max	Returns the largest of all elements of an array. Operators.max is used to compare the elements.
min	Returns the smallest of all elements of an array. Operators.min is used to compare the elements.
ofList	Creates an array from the supplied list.
ofSeq	Creates an array from the supplied enumerable object.
partition	Splits an array into two arrays, one containing the elements for which the supplied condition returns true, and the other containing those for which it returns false.
rev	Reverses the order of the elements in a supplied array.
sort	Sorts the elements of an array and returns a new array. Operators.compare is used to compare the elements.
sub	Creates an array that contains the sup<plied subrange, which is specified by starting index and length.
sum	Returns the sum of the elements in the array.
toList	Converts the supplied array to a list.
toSeq	Views the supplied array as a sequence.
unzip	Splits an array of tuple pairs into a tuple of two arrays.
zeroCreate	Creates an array whose elements are all initially zero.
zip	Combines two arrays into an array of tuples that have two elements. The two arrays must have equal lengths; otherwise, System.ArgumentException is raised.

Table 10.1: Some built-in procedures in the Array module for arrays (from `https://msdn.microsoft.com/en-us/visualfsharpdocs/conceptual/fsharp-core-library-reference`)

```
let square a = a * a

printArray A
let B = Array.map square A
printArray A
printArray B
```

```
1 2 3 4 5
1 2 3 4 5
1 4 9 16 25
```
Listing 10.4: arrayReassignModule.fsx -

and the `flowForListsIndex.fsx` program can be written using arrays as,

```
let courseGrades =
    ["Introduction to programming", 95;
     "Linear algebra", 80;
     "User Interaction", 85;]

let A = Array.ofList courseGrades
let printCourseNGrade (title, grade) =
  printfn "Course: %s, Grade: %d" title grade
Array.iter printCourseNGrade A
let (titles,grades) = Array.unzip A
let avg =  (float (Array.sum grades)) / (float grades.Length)
printfn "Average grade: %g" avg
```

```
Course: Introduction to programming, Grade: 95
Course: Linear algebra, Grade: 80
Course: User Interaction, Grade: 85
Average grade: 86.6667
```
Listing 10.5: flowForListsIndexModule.fsx -

Both cases avoid the use of variables and side-effects which is a big advantage for code safety.

10.3.2 Multidimensional Arrays

Higher dimensional arrays can be created as arrays of arrays (of arrays . . .). These are known as *jagged arrays*, since there is no inherent control of that all sub-arrays are of similar size. E.g., the following   · jagged arrays is a jagged array of increasing width,

```
let A = [| for n in 1..3 do yield [| 1 .. n |] |]

let printArrayOfArrays (a : int array array) =
  for i = 0 to a.Length - 1 do
    for j = 0 to a.[i].Length - 1 do
      printf "%d " a.[i].[j]
    printf "\n"

printArrayOfArrays A
```

```
1
1 2
1 2 3
```
Listing 10.6: arrayJagged.fsx -

Indexing arrays of arrays is done sequentially, in the sense that in the above example, the number of outer arrays is `a.Length`, `a.[i]` is the i'th array, the length of the i'th array is `a.[i].Length`, and the j'th element of the i'th array is thus `a.[i].[j]`. Often 2 dimensional square arrays are used, which can be implemented as a jagged array as,

```
let pownArray  (a : int array) p =
  for i = 0 to a.Length - 1 do
    a.[i] <- pown a.[i] p
  a

let A = [| for n in 1..3 do yield (pownArray [| 1 .. 4 |] n ) |]

let printArrayOfArrays (a : int array array) =
  for i = 0 to a.Length - 1 do
    for j = 0 to a.[i].Length - 1 do
      printf "%2d " a.[i].[j]
    printf "\n"

printArrayOfArrays A
```

```
 1  2  3  4
 1  4  9 16
 1  8 27 64
```

Listing 10.7: arrayJaggedSquare.fsx -

In fact, square arrays of dimensions 2 to 4 are so common that fsharp has built-in modules for their support. In the following describe Array2D. The workings of Array3D and Array4D are very similar. An example of creating the same 2 dimensional array as above but as an `Array2D` is,

```
let A = Array2D.create 3 4 0
for i = 0 to (Array2D.length1 A) - 1 do
  for j = 0 to (Array2D.length2 A) - 1 do
    A.[i,j] <- pown (j + 1) (i + 1)

let printArray2D (a : int [,]) =
  for i = 0 to (Array2D.length1 a) - 1 do
    for j = 0 to (Array2D.length2 a) - 1 do
      printf "%2d " a.[i, j]
    printf "\n"

printArray2D A
```

```
 1  2  3  4
 1  4  9 16
 1  8 27 64
```

Listing 10.8: array2D.fsx -

Notice that the indexing uses a slightly different notation '`[,]`' and the length functions are also slightly different. The statement `A.Length` would return the total number of elements in the array, in this case 12.[2]

There are a bit few built-in procedures for 2 dimensional array types, some of which are summarized in Table 10.2

10.4   Sequences

----

[2]**note that `A.[1,*]` is a Array but `A.[1..1,*]` is an Array2D.**

blit	Reads a range of elements from one array and writes them into another.
copy	Creates an array that contains the elements of the supplied array.
create	Creates an array whose elements are all initially the supplied value.
iter	Applies the supplied function to each element of an array.
length1	Returns the length of an array in the first dimension.
length2	Returns the length of an array in the second dimension.
map	Creates an array whose elements are the results of applying the supplied function to each of the elements of a supplied array.
mapi	
zeroCreate	Creates an array whose elements are all initially zero.

Table 10.2: Some built-in procedures in the Array2D module for arrays (from `https://msdn.microsoft.com/en-us/visualfsharpdocs/conceptual/fsharp-core-library-reference`)

Chapter 15

The Collection

15.1 `System.String`

The list of built-in methods accessible with the dot notation is defined in `System.String` class and is long. Here follows short descriptions of some useful methods:

`Compare(String, String)` Compares two specified String objects and returns an integer that indicates their relative position in the sort order.

`CompareOrdinal(String, String)` Compares two specified String objects by evaluating the numeric values of the corresponding Char objects in each string.

`CompareOrdinal(String, Int32, String, Int32, Int32)` Compares substrings of two specified String objects by evaluating the numeric values of the corresponding Char objects in each substring.

`CompareTo(Object)` Compares this instance with a specified Object and indicates whether this instance precedes, follows, or appears in the same position in the sort order as the specified Object.

`CompareTo(String)` Compares this instance with a specified String object and indicates whether this instance precedes, follows, or appears in the same position in the sort order as the specified String.

`Concat(Object)` Creates the string representation of a specified object.

`Concat(Object[])` Concatenates the string representations of the elements in a specified Object array.

`Concat(IEnumerable(String))` Concatenates the members of a constructed IEnumerable(T) collection of type String.

`Concat(String[])` Concatenates the elements of a specified String array.

`Concat(Object, Object)` Concatenates the string representations of two specified objects.

`Concat(String, String)` Concatenates two specified instances of String.

`Concat(Object, Object, Object)` Concatenates the string representations of three specified objects.

`Concat(String, String, String)` Concatenates three specified instances of String.

`Concat(Object, Object, Object, Object)` Concatenates the string representations of four specified objects and any objects specified in an optional variable length parameter list.

`Concat(String, String, String, String)` Concatenates four specified instances of String.

`Concat(T)(IEnumerable(T))` Concatenates the members of an IEnumerable(T) implementation.

`Contains` Returns a value indicating whether the specified String object occurs within this string.

`Copy` Creates a new instance of String with the same value as a specified String.

`CopyTo` Copies a specified number of characters from a specified position in this instance to a specified position in an array of Unicode characters.

`EndsWith(String)` Determines whether the end of this string instance matches the specified string.

`EndsWith(String, StringComparison)` Determines whether the end of this string instance matches the specified string when compared using the specified comparison option.

`EndsWith(String, Boolean, CultureInfo)` Determines whether the end of this string instance matches the specified string when compared using the specified culture.

`Equals(Object)` Determines whether this instance and a specified object, which must also be a String object, have the same value. (Overrides Object.Equals(Object).)

`Equals(String)` Determines whether this instance and another specified String object have the same value.

`Equals(String, String)` Determines whether two specified String objects have the same value.

`Equals(String, StringComparison)` Determines whether this string and a specified String object have the same value. A parameter specifies the culture, case, and sort rules used in the comparison.

`Equals(String, String, StringComparison)` Determines whether two specified String objects have the same value. A parameter specifies the culture, case, and sort rules used in the comparison.

`Finalize` Allows an object to try to free resources and perform other cleanup operations before it is reclaimed by garbage collection. (Inherited from Object.)

`Format(String, Object)` Replaces one or more format items in a specified string with the string representation of a specified object.

`Format(String, Object[])` Replaces the format item in a specified string with the string representation of a corresponding object in a specified array.

`Format(IFormatProvider, String, Object[])` Replaces the format item in a specified string with the string representation of a corresponding object in a specified array. A specified parameter supplies culture-specific formatting information.

`Format(String, Object, Object)` Replaces the format items in a specified string with the string representation of two specified objects.

`Format(String, Object, Object, Object)` Replaces the format items in a specified string with the string representation of three specified objects.

`GetEnumerator` Retrieves an object that can iterate through the individual characters in this string.

`GetHashCode` Returns the hash code for this string. (Overrides Object.GetHashCode().)

`GetType` Gets the Type of the current instance. (Inherited from Object.)

`GetTypeCode` Returns the TypeCode for class String.

`IndexOf(Char)` Reports the zero-based index of the first occurrence of the specified Unicode character in this string.

`IndexOf(String)` Reports the zero-based index of the first occurrence of the specified string in this instance.

`IndexOf(Char, Int32)` Reports the zero-based index of the first occurrence of the specified Unicode character in this string. The search starts at a specified character position.

`IndexOf(String, Int32)` Reports the zero-based index of the first occurrence of the specified string in this instance. The search starts at a specified character position.

`IndexOf(String, StringComparison)` Reports the zero-based index of the first occurrence of the specified string in the current String object. A parameter specifies the type of search to use for the specified string.

`IndexOf(Char, Int32, Int32)` Reports the zero-based index of the first occurrence of the specified character in this instance. The search starts at a specified character position and examines a specified number of character positions.

`IndexOf(String, Int32, Int32)` Reports the zero-based index of the first occurrence of the specified string in this instance. The search starts at a specified character position and examines a specified number of character positions.

`IndexOf(String, Int32, StringComparison)` Reports the zero-based index of the first occurrence of the specified string in the current String object. Parameters specify the starting search position in the current string and the type of search to use for the specified string.

`IndexOf(String, Int32, Int32, StringComparison)` Reports the zero-based index of the first occurrence of the specified string in the current String object. Parameters specify the starting search position in the current string, the number of characters in the current string to search, and the type of search to use for the specified string.

`IndexOfAny(Char[])` Reports the zero-based index of the first occurrence in this instance of any character in a specified array of Unicode characters.

`IndexOfAny(Char[], Int32)` Reports the zero-based index of the first occurrence in this instance of any character in a specified array of Unicode characters. The search starts at a specified character position.

`IndexOfAny(Char[], Int32, Int32)` Reports the zero-based index of the first occurrence in this instance of any character in a specified array of Unicode characters. The search starts at a specified character position and examines a specified number of character positions.

`Insert` Returns a new string in which a specified string is inserted at a specified index position in this instance.

`Intern` Retrieves the system's reference to the specified String.

`IsInterned` Retrieves a reference to a specified String.

`IsNormalized()` Indicates whether this string is in Unicode normalization form C.

`IsNormalized(NormalizationForm)` Indicates whether this string is in the specified Unicode normalization form.

`IsNullOrEmpty` Indicates whether the specified string is a null reference (Nothing in Visual Basic) or an Empty string.

`IsNullOrWhiteSpace` Indicates whether a specified string is a null reference (Nothing in Visual Basic), empty, or consists only of white-space characters.

`Join(String, IEnumerable(String))` Concatenates the members of a constructed IEnumerable(T) collection of type String, using the specified separator between each member.

`Join(String, Object[])` Concatenates the elements of an object array, using the specified separator between each element.

`Join(String, String[])` Concatenates all the elements of a string array, using the specified separator between each element.

`Join(String, String[], Int32, Int32)` Concatenates the specified elements of a string array, using the specified separator between each element.

`Join(T)(String, IEnumerable(T))` Concatenates the members of a collection, using the specified separator between each member.

`LastIndexOf(Char)` Reports the zero-based index position of the last occurrence of a specified Unicode character within this instance.

`LastIndexOf(String)` Reports the zero-based index position of the last occurrence of a specified string within this instance.

`LastIndexOf(Char, Int32)` Reports the zero-based index position of the last occurrence of a specified Unicode character within this instance. The search starts at a specified character position.

`LastIndexOf(String, Int32)` Reports the zero-based index position of the last occurrence of a specified string within this instance. The search starts at a specified character position.

`LastIndexOf(String, StringComparison)` Reports the zero-based index of the last occurrence of a specified string within the current String object. A parameter specifies the type of search to use for the specified string.

`LastIndexOf(Char, Int32, Int32)` Reports the zero-based index position of the last occurrence of the specified Unicode character in a substring within this instance. The search starts at a specified character position and examines a specified number of character positions.

`LastIndexOf(String, Int32, Int32)` Reports the zero-based index position of the last occurrence of a specified string within this instance. The search starts at a specified character position and examines a specified number of character positions.

`LastIndexOf(String, Int32, StringComparison)` Reports the zero-based index of the last occurrence of a specified string within the current String object. Parameters specify the starting search position in the current string, and type of search to use for the specified string.

`LastIndexOf(String, Int32, Int32, StringComparison)` Reports the zero-based index position of the last occurrence of a specified string within this instance. Parameters specify the starting search position in the current string, the number of characters in the current string to search, and the type of search to use for the specified string.

`LastIndexOfAny(Char[])` Reports the zero-based index position of the last occurrence in this instance of one or more characters specified in a Unicode array.

`LastIndexOfAny(Char[], Int32)` Reports the zero-based index position of the last occurrence in this instance of one or more characters specified in a Unicode array. The search starts at a specified character position.

`LastIndexOfAny(Char[], Int32, Int32)` Reports the zero-based index position of the last occurrence in this instance of one or more characters specified in a Unicode array. The search starts at a specified character position and examines a specified number of character positions.

`MemberwiseClone` Creates a shallow copy of the current Object. (Inherited from Object.)

`Normalize()` Returns a new string whose textual value is the same as this string, but whose binary representation is in Unicode normalization form C.

`Normalize(NormalizationForm)` Returns a new string whose textual value is the same as this string, but whose binary representation is in the specified Unicode normalization form.

`PadLeft(Int32)` Returns a new string that right-aligns the characters in this instance by padding them with spaces on the left, for a specified total length.

`PadLeft(Int32, Char)` Returns a new string that right-aligns the characters in this instance by padding them on the left with a specified Unicode character, for a specified total length.

`PadRight(Int32)` Returns a new string that left-aligns the characters in this string by padding them with spaces on the right, for a specified total length.

`PadRight(Int32, Char)` Returns a new string that left-aligns the characters in this string by padding them on the right with a specified Unicode character, for a specified total length.

`Remove(Int32)` Returns a new string in which all the characters in the current instance, beginning at a specified position and continuing through the last position, have been deleted.

`Remove(Int32, Int32)` Returns a new string in which a specified number of characters in this instance beginning at a specified position have been deleted.

`Replace(Char, Char)` Returns a new string in which all occurrences of a specified Unicode character in this instance are replaced with another specified Unicode character.

`Replace(String, String)` Returns a new string in which all occurrences of a specified string in the current instance are replaced with another specified string.

`Split(Char[])` Returns a string array that contains the substrings in this instance that are delimited by elements of a specified Unicode character array.

`Split(Char[], Int32)` Returns a string array that contains the substrings in this instance that are delimited by elements of a specified Unicode character array. A parameter specifies the maximum number of substrings to return.

`Split(Char[], StringSplitOptions)` Returns a string array that contains the substrings in this string that are delimited by elements of a specified Unicode character array. A parameter specifies whether to return empty array elements.

`Split(String[], StringSplitOptions)` Returns a string array that contains the substrings in this string that are delimited by elements of a specified string array. A parameter specifies whether to return empty array elements.

`Split(Char[], Int32, StringSplitOptions)` Returns a string array that contains the substrings in this string that are delimited by elements of a specified Unicode character array. Parameters specify the maximum number of substrings to return and whether to return empty array elements.

`Split(String[], Int32, StringSplitOptions)` Returns a string array that contains the substrings in this string that are delimited by elements of a specified string array. Parameters specify the maximum number of substrings to return and whether to return empty array elements.

`StartsWith(String)` Determines whether the beginning of this string instance matches the specified string.

`StartsWith(String, StringComparison)` Determines whether the beginning of this string instance matches the specified string when compared using the specified comparison option.

`StartsWith(String, Boolean, CultureInfo)` Determines whether the beginning of this string instance matches the specified string when compared using the specified culture.

`Substring(Int32)` Retrieves a substring from this instance. The substring starts at a specified character position.

`Substring(Int32, Int32)` Retrieves a substring from this instance. The substring starts at a specified character position and has a specified length.

`ToCharArray()` Copies the characters in this instance to a Unicode character array.

`ToCharArray(Int32, Int32)` Copies the characters in a specified substring in this instance to a Unicode character array.

`ToLower()` Returns a copy of this string converted to lowercase.

`ToLower(CultureInfo)` Returns a copy of this string converted to lowercase, using the casing rules of the specified culture.

`ToLowerInvariant` Returns a copy of this String object converted to lowercase using the casing rules of the invariant culture.

`ToString()` Returns this instance of String; no actual conversion is performed. (Overrides Object.ToString().)

`ToString(IFormatProvider)` Returns this instance of String; no actual conversion is performed.

`ToUpper()` Returns a copy of this string converted to uppercase.

`ToUpper(CultureInfo)` Returns a copy of this string converted to uppercase, using the casing rules of the specified culture.

`ToUpperInvariant` Returns a copy of this String object converted to uppercase using the casing rules of the invariant culture.

`Trim()` Removes all leading and trailing white-space characters from the current String object.

`Trim(Char[])` Removes all leading and trailing occurrences of a set of characters specified in an array from the current String object.

`TrimEnd` Removes all trailing occurrences of a set of characters specified in an array from the current String object.

`TrimStart` Removes all leading occurrences of a set of characters specified in an array from the current String object.

Chapter 16

Imperative programming

16.1 Introduction

Imperativ programming focusses on how a problem is to be solved as a list of *statements* and and a set of *states*, where states may change over time. An example is a baking recipe, e.g.,

1. Mix yeast with water

2. Stir in salt, oil, and flour

3. Knead until the dough has a smooth surface

4. Let the dough rise until it has double size

5. Shape dough into a loaf

6. Let the loaf rise until double size

7. Bake in oven until the bread is golden brown

· Imperativ
  programming
· statements
· states

Each line in this example consists of one or more statements that are to be executed, and while executing them states such as size of the dough, color of the bread changes, and some execution will halt execution until certain conditions of these states are fulfilled, e.g., the bread will not be put into the oven for baking before it has risen sufficiently.

Statements may be grouped into procedures, and structuring imperative programs heavily into procedures is called *Procedural programming*, which is sometimes considered as a separate paradigm from imperative programming. *Object oriented programming* is an extension of imperative programming, where statements and states are grouped into classes and will be treated elsewhere.

· Procedural
  programming
· Object oriented
  programming
· machine code

Almost all computer hardware is designed for *machine code*, which is a common term used for many low-level computer programming language, and almost all machine langues follow the imperative programming paradigm.

Functional programming may be considered a subset of imperative programming, in the sense that functional programming does not include the concept of a state, or one may think of functional programming as only have one unchanging state. Functional programming has also a bigger focus on what should be solved, by declaring rules but not explicitly listing statements describing how these rules should be combined and executed in order to solve a given problem. Functional programming will be treated elsewhere.

· Functional
  programming

16.2 Generating random texts

16.2.1 0'th order statistics

```
let histToCumulativeProbability hist =
  let appendSum (acc : float array) (elem : int) =
    let sum =
      if acc.Length = 0 then

Appendix A

Number systems on the computer

A.1 Binary numbers

Humans like to use the *decimal number* system for representing numbers. Decimal numbers are *base* 10 means that for a number consisting of a sequence of digits separated by a *decimal point*, where each *digit* can have values $d \in \{0, 1, 2, \ldots, 9\}$ and the weight of each digit is proportional to its place in the sequence of digits w.r.t. the decimal point, i.e., the number $357.6 = 3 \cdot 10^2 + 5 \cdot 10^1 + 7 \cdot 10^0 + 6 \cdot 10^{-1}$ or in general:

$$v = \sum_{i=-m}^{n} d_i 10^i \tag{A.1}$$

· decimal number
· base
· decimal point
· digit

The basic unit of information in almost all computers is the binary digit or *bit* for short. A *binary* number consists of a sequence of binary digits separated by a decimal point, where each digit can have values $b \in \{0, 1\}$, and the base is 2. The general equation is,

$$v = \sum_{i=-m}^{n} b_i 2^i \tag{A.2}$$

· bit
· binary

and examples are $1011.1_2 = 1 \cdot 2^3 + 0 \cdot 2^2 + 1 \cdot 2^1 + 1 \cdot 2^0 + 1 \cdot 2^{-1} = 11.5$. Notice that we use subscript 2 to denote a binary number, while no subscript is used for decimal numbers. Due to typical organization of computer memory, 8 binary digits is called a *byte*, and 32 digits a *word*.
Other number systems are often used, e.g., *octal* numbers, which are base 8 numbers, where each digit is $o \in \{0, 1, \ldots, 7\}$. Octals are useful short-hand for binary, since 3 binary digits maps to the set of octal digits. Likewise, *hexadecimal* numbers are base 16 with digits $h \in \{0, 1, 2, 3, 4, 5, 6, 7, 8, 9, a, b, c, d, e, f\}$, such that $a_{16} = 10$, $b_{16} = 11$ and so on. Hexadecimals are convenient since 4 binary digits map directly to the set of octal digits. Thus $367 = 101101111_2 = 557_8 = 16f_{16}$. A list of the intergers 0–63 is various bases is given in Table A.1.

· byte
· word
· octal
· hexadecimal

A.2 IEEE 754 floating point standard

The set of real numbers also called *reals* includes all fractions and irrational numbers. It is infinite in size both in the sense that there is no largest nor smallest number and between any 2 given numbers there are infinitely many numbers. Reals are widely used for calculation, but since any computer only has finite memory, it is impossible to represent all possible reals. Hence, any computation performed on a computer with reals must rely on approximations. *IEEE 754 double precision floating-point format* (*binary64*), known as a *double*, is a standard for representing an approximation of reals using 64 bits. These bits are divided into 3 parts: sign, exponent and fraction,

$$s\, e_1 e_2 \ldots e_{11}\, m_1 m_2 \ldots m_{52},$$

31	11111	37	1f	63	111111	77	3f

Table A.1: A list of the intergers 0–63 in decimal, binary, octal, and hexadecimal.

where s, e_i, and m_j are binary digits. The bits are converted to a number using the equation by first calculating the exponent e and the mantissa m,

$$e = \sum_{i=1}^{11} e_i 2^{11-i}, \tag{A.3}$$

$$m = \sum_{j=1}^{52} m_j 2^{-j}. \tag{A.4}$$

I.e., the exponent is an integer, where $0 \le e < 2^{11}$, and the mantissa is a rational, where $0 \le m < 1$. For most combinations of e and m the real number v is calculated as,

$$v = (-1)^s \left(1 + m\right) 2^{e-1023} \tag{A.5}$$

with the exception that

	$m = 0$	$m \ne 0$
$e = 0$	$v = (-1)^s\, 0$ (signed zero)	$v = (-1)^s\, m 2^{1-1023}$ (subnormals)
$e = 2^{11} - 1$	$v = (-1)^s\, \infty$	$v = (-1)^s\, \text{NaN}$ (not a number)

· subnormals
· NaN
· not a number

where $e = 2^{11} - 1 = 11111111111_2 = 2047$. The largest and smallest number that is not infinity is thus

$$e = 2^{11} - 2 = 2046 \tag{A.6}$$

$$m = \sum_{j=1}^{52} 2^{-j} = 1 - 2^{-52} \simeq 1. \tag{A.7}$$

$$v_{\text{max}} = \pm \left(2 - 2^{-52}\right) 2^{1023} \simeq \pm 2^{1024} \simeq \pm 10^{308} \tag{A.8}$$

The density of numbers varies in such a way that when $e - 1023 = 52$, then

$$v = (-1)^s \left(1 + \sum_{j=1}^{52} m_j 2^{-j}\right) 2^{52} \tag{A.9}$$

$$= \pm \left(2^{52} + \sum_{j=1}^{52} m_j 2^{-j} 2^{52}\right) \tag{A.10}$$

$$= \pm \left(2^{52} + \sum_{j=1}^{52} m_j 2^{52-j}\right) \tag{A.11}$$

$$\stackrel{k=52-j}{=} \pm \left(2^{52} + \sum_{k=51}^{0} m_{52-k} 2^k\right) \tag{A.12}$$

which are all integers in the range $2^{52} \le |v| < 2^{53}$. When $e - 1023 = 53$, then the same calculation gives

$$v \stackrel{k=53-j}{=} \pm \left(2^{53} + \sum_{k=52}^{1} m_{53-k} 2^k\right) \tag{A.13}$$

which are every second integer in the range $2^{53} \le |v| < 2^{54}$, and so on for larger e. When $e - 1023 = 51$, then the same calculation gives,

$$v \stackrel{k=51-j}{=} \pm \left(2^{51} + \sum_{k=50}^{-1} m_{51-k} 2^k\right) \tag{A.14}$$

which gives a distance between numbers of $1/2$ in the range $2^{51} \leq |v| < 2^{52}$, and so on for smaller e. Thus we may conclude that the distance between numbers in the interval $2^n \leq |v| < 2^{n+1}$ is 2^{n-52}, for $-1022 = 1 - 1023 \leq n < 2046 - 1023 = 1023$. For subnormals the distance between numbers are

$$v = (-1)^s \left(\sum_{j=1}^{52} m_j 2^{-j} \right) 2^{-1022} \tag{A.15}$$

$$= \pm \left(\sum_{j=1}^{52} m_j 2^{-j} 2^{-1022} \right) \tag{A.16}$$

$$= \pm \left(\sum_{j=1}^{52} m_j 2^{-j-1022} \right) \tag{A.17}$$

$$\overset{k=-j-1022}{=} \pm \left(\sum_{j=-1023}^{-1074} m_{-k-1022} 2^k \right) \tag{A.18}$$

which gives a distance between numbers of $2^{-1074} \simeq 10^{-323}$ in the range $0 < |v| < 2^{-1022} \simeq 10^{-308}$.

Appendix B

Commonly used character sets

Letters, digits, symbols and space are the core of how we store data, write programs, and comunicate with computers and each others. These symbols are in short called characters, and represents a mapping between numbers, also known as codes, and a pictorial representation of the character. E.g., the ASCII code for the letter 'A' is 65. These mappings are for short called character sets, and due to differences in natural languages and symbols used across the globe, many different character sets are in use. E.g., the English alphabet contains the letters 'a' to 'z', which is shared by many other European languages, but which have other symbols and accents for example, Danish has further the letters 'æ', 'ø', and 'å'. Many non-european languages have completely different symbols, where Chinese character set is probably the most extreme, where some definitions contains 106,230 different characters albeit only 2,600 are included in the official Chinese language test at highest level.

Presently, the most common character set used is Unicode Transformation Format (UTF), whose most popular encoding schemes are 8-bit (UTF-8) and 16-bit (UTF-16). Many other character sets exists, and many of the later builds on the American Standard Code for Information Interchange (ASCII). The ISO-8859 codes were an intermediate set of character sets that are still in use, but which is greatly inferior to UTF. Here we will briefly give an overview of ASCII, ISO-8859-1 (Latin1), and UTF.

B.1 ASCII

The *American Standard Code for Information Interchange* (*ASCII*) [4], is a 7 bit code tuned for the letters of the english language, numbers, punctuation symbols, control codes and space, see Tables B.1 and B.2. The first 32 codes are reserved for non-printable control characters to control printers and similar devices or to provide meta-information. The meaning of each control characters is not universally agreed upon.

· American Standard Code for Information Interchange

· ASCII

The code order is known as *ASCIIbetical order*, and it is sometimes used to perform arithmetic on codes, e.g., an upper case letter with code c may be converted to lower case by adding 32 to its code. The ASCIIbetical order also has consequence for sorting, i.e., when sorting characters according to their ASCII code, then 'A' comes before 'a', which comes before the symbol '{'.

· ASCIIbetical order

B.2 ISO/IEC 8859

The ISO/IEC 8859 report `http://www.iso.org/iso/catalogue_detail?csnumber=28245` defines 10 sets of codes specifying up to 191 codes and graphic characters using 8 bits. Set 1 also known as ISO/IEC 8859-1, Latin alphabet No. 1, or *Latin1* covers many European languages and is designed to be compatible with ASCII, such that code for the printable characters in ASCII are the same in ISO 8859-1. In Table B.3 is shown the characters above 7e. Codes 00-1f and 7f-9f are undefined in ISO 8859-1.

Table B.1: ASCII

B.3 Unicode

Unicode is a character standard defined by the Unicode Consortium, `http://unicode.org` as the *Unicode Standard*. Unicode allows for 1,114,112 different codes. Each code is called a *code point*, which represents an abstract character. However, not all abstract characters requires a unit of several code points to be specified. Code points are divided into 17 planes each with $2^{16} = 65,536$ code points. Planes are further subdivided into named *blocks*. The first plane is called the *Basic Multilingual plane* and it are the first 128 code points is called the *Basic Latin block* and are identical to ASCII, see Table B.1, and code points 128-255 is called the *Latin-1 Supplement block*, and are identical to the upper range of ISO 8859-1, see Table B.3. Each code-point has a number of attributes such as the *unicode general category*. Presently more than 128,000 code points covering 135 modern and historic writing systems, and obtained at `http://www.unicode.org/Public/UNIDATA/UnicodeData.txt`, which includes the code point, name, and general category.

A unicode code point is an abstraction from the encoding and the graphical representation of a character. A code point is written as "U+" followed by its hexadecimal number, and for the Basic Multilingual plane 4 digits are used, e.g., the code point with the unique name LATIN CAPITAL LETTER A has the unicode code point is "U+0041", and is in this text it is visualized as 'A'. More digits are used for code points of the remaining planes.

The general category is used in grammars to specify legal characters, e.g., in naming identifiers in F#. Some categories and their letters in the first 256 code points are shown in Table B.5.

To store and retrieve code points, they must be encoded and decoded. A common encoding is *UTF-8*, which encodes code points as 1 to 4 bytes, and which is backward-compatible with ASCII and ISO 8859-1. Hence, in all 3 coding systems the character with code 65 represents the character 'A'. Another popular encoding scheme is *UTF-16*, which encodes characters as 2 or 4 bytes, but which is not backward-compatible with ASCII or ISO 8859-1. UTF-16 is used internally in many compiles, interpreters and operating systems.

· Unicode Standard
· code point
· blocks
· Basic Multilingual plane
· Basic Latin block
· Latin-1 Supplement block
· unicode general category

· UTF-8

· UTF-16

Code	Description
NUL	Null
SOH	Start of heading
STX	Start of text
ETX	End of text
EOT	End of transmission
ENQ	Enquiry
ACK	Acknowledge
BEL	Bell
BS	Backspace
HT	Horizontal tabulation
LF	Line feed
VT	Vertical tabulation
FF	Form feed
CR	Carriage return
SO	Shift out
SI	Shift in
DLE	Data link escape
DC1	Device control one
DC2	Device control two
DC3	Device control three
DC4	Device control four
NAK	Negative acknowledge
SYN	Synchronous idle
ETB	End of transmission block
CAN	Cancel
EM	End of medium
SUB	Substitute
ESC	Escape
FS	File separator
GS	Group separator
RS	Record separator
US	Unit separator
SP	Space
DEL	Delete

Table B.2: ASCII symbols.

x0+0x	80	90	A0	B0	C0	D0	E0	F0

0f			¯	¿	Ï	ß	ï	ÿ

Table B.3: ISO-8859-1 (latin1) non-ASCII part. Note that the codes 7f – 9f are undefined.

Code	Description
NBSP	Non-breakable space
SHY	Soft hypen

Table B.4: ISO-8859-1 special symbols.

General category	Code points	Name
Lu	U+0041–U+005A, U+00C0–U+00D6, U+00D8–U+00DE	Upper case letters
Ll	U+0061–U+007A, U+00B5, U+00DF–U+00F6, U+00F8–U+00FF	Lower case letter
Lt	None	Digraphic letter, with first part uppercase
Lm	None	Modifier letter
Lo	U+00AA, U+00BA	Gender ordinal indicator
Nl	None	Letterlike numeric character
Pc	U+005F	Low line
Mn	None	Nonspacing combining mark
Mc	None	Spacing combining mark
Cf	U+00AD	Soft Hyphen

Table B.5: Some general categories for the first 256 code points.

Appendix C

A brief introduction to Extended Backus-Naur Form

Extended Backus-Naur Form (*EBNF*) is a language to specify programming languages in. The name is a tribute to John Backus who used it to describe the syntax of ALGOL58 and Peter Nauer for his work on ALGOL 60.

An EBNF consists of *terminal symbols* and *production rules*. Examples of typical terminal symbol are characters, numbers, punctuation marks, and whitespaces, e.g.,

```
digit = "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9" ;
```

A production rule specifies a method of combining other production rules and terminal symbols, e.g.,

```
number = { digit } ;
```

A proposed standard for EBNF (proposal ISO/IEC 14977, `http://www.cl.cam.ac.uk/~mgk25/iso-14977.pdf`) is,

'=' definition, e.g.,

```
zero = "0" ;
```

here `zero` is the terminal symbol `0`.

',' concatenation, e.g.,

```
one = "1" ;
eleven = one , one ;
```

here `eleven` is the terminal symbol `11`.

';' termination of line

'|' alternative options, e.g.,

```
digit = "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9" ;
```

here `digit` is the single character terminal symbol, such as `3`.

'[...]' optional, e.g.,

```
zero = "0" ;
nonZeroDigit = "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9" ;
nonZero = [ zero ], nonZeroDigit
```

here **nonZero** is a non-zero digit possibly preceded by zero, such as `02`.

'{ ... }' repetition zero or more times, e.g.,

```
digit = "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9" ;
number = digit, { digit }
```

here `number` is a word consisting of 1 or more digits, such as 12.

'(...)' grouping, e.g.,

```
digit = "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9" ;
number = digit, { digit }
expression = number, { ( "+" | "-" ), number };
```

here `expression` is a number or a sum of numbers such as 3 + 5.

'" ... "' a terminal string, e.g.,

```
string = "abc"' ;
```

"' ... '" a terminal string, e.g.,

```
string = 'abc' ;
```

'(* ... *)' a comment (* ... *)

```
(* a binary digit *) digit = "0" | "1" (* from this all numbers may be constructed *) ;
```

Everything inside the comments are not part of the formal definition.

'? ... ?' special sequence, a notation reserved for future extensions of EBNF.

'-' exception, e.g.,

```
letter = "A" | "B" | "C" | "D" | "E" | "F" | "G" | "H"
   | "I" | "J" | "K" | "L" | "M" | "N" | "O" | "P" | "Q"
   | "R" | "S" | "T" | "U" | "V" | "W" | "X" | "Y" | "Z" ;
vowel = "A" | "E" | "I" | "O" | "U" ;
consonant = letter - vowel ;
```

here `consonant` are all letters except vowels.

The proposal allows for identifies that includes space, but often a reduced form is used, where identifiers are single words, in which case the concatenation symbol , is omitted. Likewise, the termination symbol ; is often replaced with the new-line character, and if long lines must be broken, then indentation is used to signify continuation.

In this relaxed EBNF, the EBNF syntax itself can be expressed in EBNF as,

```
letter = "A" | "B" | "C" | "D" | "E" | "F" | "G" | "H"
   | "I" | "J" | "K" | "L" | "M" | "N" | "O" | "P" | "Q"
   | "R" | "S" | "T" | "U" | "V" | "W" | "X" | "Y" | "Z"
   | "a" | "b" | "c" | "d" | "e" | "f" | "g" | "h"
   | "i" | "j" | "k" | "l" | "m" | "n" | "o" | "p" | "q"
   | "r" | "s" | "t" | "u" | "v" | "w" | "x" | "y" | "z"
digit = "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9"
symbol = "[" | "]" | "{" | "}" | "(" | ")" | "<" | ">"
   | "'" | '"' | "=" | "|" | "." | "," | ";"
underscore = "_"
identifier = letter  { letter | digit | underscore }
character = letter | digit | symbol | underscore
string = character  { character }
```

```
terminal = "'"  string  "'" | '"'  string  '"'
rhs = identifier
    | terminal
    | "["  rhs  "]"
    | "{"  rhs  "}"
    | "("  rhs  ")"
    | rhs  "|"  rhs
(*  | rhs  ","  rhs  *)
rule = identifier  "="  rhs  (* ";" *)
grammar = rule { rule }
```

Here the comments demonstrate, the relaxed modification.
